THE COMING OF AGE OF THE ORIGIN OF SPECIES[1]

MANY of you will be familiar with the aspect of this small green-covered book. It is a copy of the first edition of the "Origin of Species," and bears the date of its production—the first of October, 1859. Only a few months, therefore, are needed to complete the full tale of twenty-one years since its birthday.

Those whose memories carry them back to this time will remember that the infant was remarkably lively, and that a great number of excellent persons mistook its manifestations of a vigorous individuality for mere naughtiness; in fact there was a very pretty turmoil about its cradle. My recollections of the period are particularly vivid; for, having conceived a tender affection for a child of what appeared to me to be such remarkable promise, I acted for some time in the capacity of a sort of under-nurse, and thus came in for my share of the storms which threatened even the very life of the young creature. For some years it was undoubtedly warm work, but considering how exceedingly unpleasant the apparition of the new-comer must have been to those who did not fall in love with him at first sight, I think it is to the credit of our age that the war was not fiercer, and that the more bitter and unscrupulous forms of opposition died away as soon as they did.

I speak of this period as of something past and gone, possessing merely a historical, I had almost said an antiquarian interest. For, during the second decade of the existence of the "Origin of Species," opposition, though by no means dead, assumed a different aspect. On the par of all those who had any reason to respect themselves, it assumed a thoroughly respectful character. By this time the dullest began to perceive that the child was not likely to perish of any congenital weakness or infantile disorder, but was growing into a stalwart personage, upon whom mere goody scoldings and threatenings with the birch-rod were quite thrown away.

[1] A Lecture delivered at the Royal Institution, Friday, March 19.

In fact, those who have watched the progress of science within the last ten years will bear me out to the full when I assert that there is no field of biological inquiry in which the influence of the "Origin of Species" is not traceable; the foremost men of science in every country are either avowed champions of its leading doctrines, or at any rate abstain from opposing them; a host of young and ardent investigators seek for and find inspiration and guidance in Mr. Darwin's great work; and the general doctrine of Evolution, to one side of which it gives expression, finds in the phenomena of biology a firm base of operations whence it may conduct its conquest of the whole realm of nature.

History warns us, however, that it is the customary fate of new truths to begin as heresies and to end as superstitions; and, as matters now stand, it is hardly rash to anticipate that, in another twenty years, the new generation, educated under the influences of the present day, will be in danger of accepting the main doctrines of the Origin of Species with as little reflection, and it may be with as little justification, as so many of our contemporaries, twenty years ago, rejected them.

Against any such a consummation let us all devoutly pray; for the scientific spirit is of more value than its products, and irrationally-held truths may be more harmful than reasoned errors. Now the essence of the scientific spirit is criticism. It tells us that to whatever doctrine claiming our ascent we should reply, Take it if you can compel it. The struggle for existence holds as much in the intellectual as in the physical world. A theory is a species of thinking, and its right to exist is coextensive with its power of resisting extinction by its rivals.

From this point of view it appears to me that it would be but a poor way of celebrating the Coming of Age of the Origin of Species were I merely to dwell upon the facts, undoubted and remarkable as they are, of its far-reaching influence and of the great following of ardent disciples who are occupied in spreading and developing its doctrines. Mere insanities and inanities have before now swollen to portentous size in the course of twenty years. Let us rather ask this prodigious change in opinion to justify itself; let us inquire whether anything has happened since 1859 which will explain, on rational grounds, why so many are worshipping that which they burned, and burning

B

that which they worshipped. It is only in this way that we shall acquire the means of judging whether the movement we have witnessed is a mere eddy of fashion, or truly one with the irreversible current of intellectual progress, and, like it, safe from retrogressive reaction.

Every belief is the product of two factors: the first is the state of the mind to which the evidence in favour of that belief is presented; and the second is the logical cogency of the evidence itself. In both these respects the history of biological science during the last twenty years appears to me to afford an ample explanation of the change which has taken place; and a brief consideration of the salient events of that history will enable us to understand why, if the "Origin of Species" appeared now, it would meet with a very different reception from that which greeted it in 1859.

One-and-twenty years ago, in spite of the work commenced by Hutton and continued with rare skill and patience by Lyell, the dominant view of the past history of the earth was catastrophic. Great and sudden physical revolutions, wholesale creations and extinctions of living beings, were the ordinary machinery of the geological epic brought into fashion by the misapplied genius of Cuvier. It was gravely maintained and taught that the end of every geological epoch was signalised by a cataclysm, by which every living being on the globe was swept away, to be replaced by a brand-new creation when the world returned to quiescence. A scheme of nature which appeared to be modelled on the likeness of a succession of rubbers of whist, at the end of each of which the players upset the table and called for a new pack, did not seem to shock anybody.

I may be wrong, but I doubt if at the present time there is a single responsible representative of these opinions left. The progress of scientific geology has elevated the fundamental principle of uniformitarianism, that the explanation of the past is to be sought in the study of the present, into the position of an axiom; and the wild speculations of the catastrophists, to which we all listened with respect a quarter of a century ago, would hardly find a single patient hearer at the present day. No physical geologist now dreams of seeking outside the ranges of known natural causes for the explanation of anything that happened millions of years ago, any more than he would be guilty of the like absurdity in regard to current events.

The effect of this change of opinion upon biological speculation is obvious. For, if there have been no periodical general physical catastrophes, what brought about the assumed general extinctions and re-creations of life which are the corresponding biological catastrophes? And if no such interruptions of the ordinary course of nature have taken place in the organic, any more than in the inorganic, world, what alternative is there to the admission of Evolution?

The doctrine of Evolution in Biology is the necessary result of the logical application of the principles of uniformitarianism to the phenomena of life. Darwin is the natural successor of Hutton and Lyell, and the "Origin of Species" the natural sequence of the "Principles of Geology."

The fundamental doctrine of the "Origin of Species," as of all forms of the theory of Evolution applied to biology, is "that the innumerable species, genera, and families of organic beings with which the world is peopled have all descended, each within its own class or group, from common parents, and have all been modified in the course of descent." [1]

And, in view of the facts of geology, it follows that all living animals and plants "are the lineal descendants of those which lived long before the Silurian epoch." [2]

It is an obvious consequence of this theory of Descent with Modification, as it is sometimes called, that all plants and animals, however different they may now be, must, at one time or other, have been connected by direct or indirect intermediate gradations, and that the appearance of isolation presented by various groups of organic beings must be unreal.

No part of Mr. Darwin's work ran more directly counter to the prepossessions of naturalists twenty years ago than this. And such prepossessions were very excusable, for there was undoubtedly a great deal to be said, at that time, in favour of the fixity of species and of the existence of great breaks, which there was no obvious or probable means of filling up, between various groups of organic beings.

For various reasons, scientific and unscientific, much had been made of the hiatus between man and the rest of the higher mammalia, and it is no wonder that issue was first joined on this part of the controversy. I have no wish to revive past and happily forgotten controversies, but I must state the simple fact that the distinctions in cerebral and other characters, which were so hotly affirmed to separate man from all other animals in 1860, have all been demonstrated to be non-existent, and that the contrary doctrine is now universally accepted and taught.

But there were other cases in which the wide structural gaps asserted to exist between one group of animals and another were by no means fictitious; and, when such structural breaks were real, Mr. Darwin could account for them only by supposing that the intermediate forms which once existed had become extinct. In a remarkable passage he says:—

"We may thus account even for the distinctness of whole classes from each other—for instance of birds from all other vertebrate animals—by the belief that many animal forms of life have been utterly lost, through which the early progenitors of birds were formerly connected with the early progenitors of the other vertebrate classes." [3]

Adverse criticism made merry over such suggestions as these. Of course it was easy to get out of the difficulty by supposing extinction; but where was the slightest evidence that such intermediate forms between birds and reptiles as the hypothesis required ever existed? And then probably followed a tirade upon this terrible forsaking of the paths of "Baconian induction."

But the progress of knowledge has justified Mr. Darwin to an extent which could hardly have been anticipated. In 1862, the specimen of *Archæopteryx*, which until the last two or three years has remained unique, was discovered; and it is an animal which, in its feathers and the greater part of its organisation, is a veritable bird, while, in other parts, it is as distinctly reptilian.

In 1868, I had the honour of bringing under your notice, in this theatre, the results of investigations made, up to that time, into the anatomical characters of certain ancient

[1] "Origin of Species," ed. 1, p. 457.
[2] "Origin of Species," ed. 1, p. 458.
[3] "Origin of Species," ed. 1, p. 431.

reptiles, which showed the nature of the modifications in virtue of which the type of the quadrupedal reptile passed into that of the bipedal bird; and abundant confirmatory evidence of the justice of the conclusions which I then laid before you has since come to light.

In 1875, the discovery of the toothed birds of the cretaceous formation in North America, by Prof. Marsh, completed the series of transitional forms between birds and reptiles, and removed Mr. Darwin's proposition that "many animal forms of life have been utterly lost, through which the early progenitors of birds were formerly connected with the early progenitors of the other vertebrate classes," from the region of hypothesis to that of demonstrable fact.

In 1859, there appeared to be a very sharp and clear hiatus between vertebrated and invertebrated animals, not only in their structure, but, what was more important, in their development. I do not think that we even yet know the precise links of connection between the two; but the investigations of Kowalewsky and others upon the development of *Amphioxus* and of the *Tunicata* prove beyond a doubt that the differences which were supposed to constitute a barrier between the two are non-existent. There is no longer any difficulty in understanding how the vertebrate type may have arisen from the invertebrate, though the full proof of the manner in which the transition was actually effected may still be lacking.

Again, in 1859, there appeared to be a no less sharp separation between the two great groups of flowering and flowerless plants. It is only subsequently that the series of remarkable investigations inaugurated by Hofmeister has brought to light the extraordinary and altogether unexpected modifications of the reproductive apparatus in the *Lycopodiaceæ*, the *Rhizocarpeæ*, and the *Gymnospermeæ*, by which the ferns and the mosses are gradually connected with the Phanerogamic division of the vegetable world.

So, again, it is only since 1859 that we have acquired that wealth of knowledge of the lowest forms of life which demonstrates the futility of any attempt to separate the lowest plants from the lowest animals, and shows that the two kingdoms of living nature have a common borderland which belongs to both or to neither.

Thus it will be observed that the whole tendency of biological investigation since 1859 has been in the direction of removing the difficulties which the apparent breaks in the series created at that time; and the recognition of gradation is the first step towards the acceptance of evolution.

As another great factor in bringing about the change of opinion which has taken place among naturalists, I count the astonishing progress which has been made in the study of embryology. Twenty years ago, not only were we devoid of any accurate knowledge of the mode of development of many groups of animals and plants, but the methods of investigation were rude and imperfect. At the present time there is no important group of organic beings the development of which has not been carefully studied, and the modern methods of hardening and section-making enable the embryologist to determine the nature of the process in each case, with a degree of minuteness and accuracy which is truly astonishing to those whose memories carry them back to the beginnings of modern histology. And the results of these embryological investigations are in complete harmony with the requirements of the doctrine of Evolution. The first beginnings of all the higher forms of animal life are similar, and however diverse their adult conditions, they start from a common foundation. Moreover the process of development of the animal or the plant from its primary egg or germ is a true process of evolution—a progress from almost formless to more or less highly organised matter, in virtue of the properties inherent in that matter.

To those who are familiar with the process of development all *à priori* objections to the doctrine of biological evolution appear childish. Any one who has watched the gradual formation of a complicated animal from the protoplasmic mass which constitutes the essential element of a frog's or a hen's egg has had under his eyes sufficient evidence that a similar evolution of the animal world from the like foundation is, at any rate, possible.

Yet another product of investigation has largely contributed to the removal of the objections to the doctrine of Evolution current in 1859. It is the proof afforded by successive discoveries that Mr. Darwin did not overestimate the imperfection of the geological record. No more striking illustration of this is needed than a comparison of our knowledge of the mammalian fauna of the Tertiary epoch in 1859 with its present condition. M. Gaudry's researches on the fossils of Pikermi were published in 1868, those of Messrs. Leidy, Marsh, and Cope on the fossils of the Western Territories of America, have appeared almost wholly since 1870; those of M. Filhol, on the phosphorites of Quercy, in 1878. The general effect of these investigations has been to introduce us to a multitude of extinct animals, the existence of which was previously hardly suspected; just as if zoologists were to become acquainted with a country, hitherto unknown, as rich in novel forms of life, as Brazil or South Africa once were to Europeans. Indeed the fossil fauna of the Western Territories of America bids fair to exceed in interest and importance all other known Tertiary deposits put together; and yet, with the exception of the case of the American tertiaries, these investigations have extended over very limited areas, and at Pikermi were confined to an extremely small space.

Such appear to me to be the chief events in the history of the progress of knowledge, during the last twenty years, which account for the changed feeling with which the doctrine of Evolution is at present regarded by those who have followed the advance of biological science in respect of those problems which bear indirectly upon that doctrine.

But all this remains mere secondary evidence. It may remove dissent, but it does not compel assent. Primary and direct evidence in favour of Evolution can be furnished only by palæontology. The geological record, so soon as it approaches completeness, must, when properly questioned, yield either an affirmative or a negative answer; if evolution has taken place, there will its mark be left; if it has not taken place, there will lie its refutation.

What was the state of matters in 1859? Let us hear Mr. Darwin, who may be trusted always to state the case against himself as strongly as possible.

"On this doctrine of the extermination of an infinitude of connecting links between the living and extinct inhabi-

tants of the world, and at each successive period between the extinct and still older species, why is not every geological formation charged with such links? Why does not every collection of fossil remains afford plain evidence of the gradation and mutation of the forms of life? We meet with no such evidence, and this is the most obvious and plausible of the many objections which may be urged against my theory."[1]

Nothing could have been more useful to the opposition than this characteristically candid avowal, twisted as it immediately was into an admission that the writer's views were contradicted by the facts of palæontology. But, in fact, Mr. Darwin made no such admission. What he says in effect is, not that palæontological evidence is against him, but that *it is not distinctly in his favour*; and without attempting to attenuate the fact, he accounts for it by the scantiness and the imperfection of that evidence.

What is the state of the case now, when, as we have seen, the amount of our knowledge respecting the mammalia of the Tertiary epoch is increased fifty-fold, and in some directions even approaches completeness?

Simply this, that if the doctrine of Evolution had not existed palæontologists must have invented it, so irresistibly is it forced upon the mind by the study of the remains of the Tertiary mammalia which have been brought to light since 1859.

Among the fossils of Pikermi, Gaudry found the successive stages by which the ancient civets passed into the more modern hyænas; through the Tertiary deposits of Western America, Marsh tracked the successive forms by which the ancient stock of the horse has passed into its present form; and innumerable less complete indications of the mode of evolution of other groups of the higher mammalia have been obtained.

In the remarkable memoir on the Phosphorites of Quercy, to which I have referred, M. Filhol describes no fewer than seventeen varieties of the genus *Cynodictis*, which fill up all the interval between the viverine animals and the bear-like dog *Amphicyon*; nor do I know any solid ground of objection to the supposition that in this *Cynodictis-Amphicyon* group we have the stock whence all the Viveridæ, Felidæ, Hyænidæ, Canidæ, and perhaps the Procyonidæ and Ursidæ, of the present fauna have been evolved. On the contrary, there is a great deal to be said in its favour.

In the course of summing up his results, M. Filhol observes[2]:—

"During the epoch of the phosphorites, great changes took place in animal forms, and almost the same types as those which now exist became defined from one another.

"Under the influence of natural conditions of which we have no exact knowledge, though traces of them are discoverable, species have been modified in a thousand ways: races have arisen which, becoming fixed, have thus produced a corresponding number of secondary species."

In 1859, language of which this is an unintentional paraphrase, occurring in the "Origin of Species," was scouted as wild speculation; at present, it is a sober statement of the conclusions to which an acute and critically-minded investigator is led by large and patient study of the facts of palæontology. I venture to repeat what I have said before, that, so far as the animal world is concerned, Evolution is no longer a speculation, but a statement of historical fact. It takes its place alongside of those accepted truths which must be taken into account by philosophers of all schools.

Thus when, on the first day of October next, the "Origin of Species" comes of age, the promise of its youth will be amply fulfilled; and we shall be prepared to congratulate the venerated author of the book, not only that the greatness of his achievement and its enduring influence upon the progress of knowledge have won him a place beside our Harvey; but, still more, that, like Harvey, he has lived long enough to outlast detraction and opposition, and to see the stone that the builders rejected become the head-stone of the corner. T. H. HUXLEY

[1] "Origin of Species, ed. 1, p. 463.
[2] This passage was omitted in the delivery of the lecture.

ON MULTIPLE SPECTRA

"Nunc age, quo motu genitalia materiai
Corpora res varias gignant, genitasque resolvant
Et qua vi facere id cogantur."
Lucretius, ii., 61–2.

"Prima moventur enim per se primordia rerum:
Inde ea, quæ parvo sunt corpora conciliatu,
Et quasi proxima sunt ad vireis principiorum,
Ictibus illorum cæcis impulsa cientur
Ipsaque, quæ porro paulo maiora, lacessunt."
Lucretius, ii. 132–6.

"It is conceivable that the various kinds of matters, now recognised in different elementary substances, may possess one and the same ultimate or atomic molecule existing in different conditions of movement.

"The essential unity of matter is an hypothesis in harmony with the equal action of gravity upon all bodies."—*Graham's Researches*, p. 299.

IN a recent paper[1] I showed that a study of the minute anatomy of spectra, both terrestrial and celestial, forces upon us the conclusion that both in the electric arc and in the hottest region of the sun the so-called chemical elements behave after the manner of compound bodies.

I then dealt more especially with the question of the basic lines in the various spectra, and it is clear that if, at any one temperature, there be some lines only truly basic in the spectrum of any element, we at once divide the lines visible at that temperature into two groups, those which are basic and those which are not. This would give a compound origin to the lines, and this is the real point.

It is now years ago since the view was first held that the elementary bodies had double spectra, that is, that each, or at all events several, under changed conditions of temperature or electric tension, gave us now a fluted spectrum and now one composed of lines.

I glimpsed the idea some time afterwards that the line spectrum was in its turn in all probability a complex whole, in other words that it was the summation of the spectra of various molecular groupings.

Recent work has to my mind not only shown that this is true, but that in the case of many bodies the complexity, and therefore the number, of the molecular groupings which give rise to that compound whole called a line spectrum, is considerable.

It is therefore important from my point of view to reconsider the evidence on which the assertion that the

[1] "On the Necessity for a New Departure in Spectrum Analysis" (NATURE, vol. xxi. p. 8).

fluted bands and the line spectrum (taken as a whole) of a substance really belong to that substance, because if we find that this must be accepted and that it can easily be explained on the view that the two kinds of spectra are produced by different molecular groupings, the fact of other molecular groupings giving rise to a complex line spectrum can be more readily accepted, contrary though it be to modern "chemical philosophy," as taught at all events in the text-books.

Plucker and Hittorf were, I believe, the first to point out that the same chemical substance, when in a state of gas or vapour, gave out different spectra under different conditions. On this point they wrote fifteen years ago:—

"The first fact which we discovered in operating with our tubes . . . was the following one:—

"*There is a certain number of elementary substances which, when differently heated, furnish two kinds of spectra of quite a different character, not having any line or any band in common.*

"The fact is important, as well with regard to theoretical conceptions as to practical applications—the more so as the passage from one kind of spectrum to the other is by no means a continuous one, but takes place abruptly. By regulating the temperature you may repeat the two spectra in any succession *ad libitum.*" (Plucker and Hittorf on the Spectra of Ignited Gases and Vapours: *Phil. Trans.* Royal Society, 1865, part i. p. 6.)

Ångström, whose name must ever be mentioned with the highest respect by any worker in spectrum analysis, was distinctly opposed to this view, and in the text which accompanies his *Spectre Normal* we find the following statement—

"Dans un Mémoire sur les spectres 'doubles' des corps élémentaires que nous publierons prochaînement, M. Thalén et moi, dans les Actes de la Société des Sciences d'Upsal, nous traiterons d'une manière suffisamment complète les questions importantes qu'on peut se proposer sur cet intéressant sujet. Pour le présent, je me borne à dire que les résultats auxquels nous sommes arrivés, ne confirment aucunement l'opinion émise par Plücker, qu'un corps élémentaire pourrait donner, suivant sa température plus ou moins élevée, des spectres tout-à-fait différents. C'est le contraire qui est exact. En effet en augmentant successivement la température, on trouve que les raies varient en intensité d'une manière très-compliquée, et que, par suite, de nouvelles raies peuvent même se présenter, si la température s'élève suffisamment. Mais, independamment de toutes ces mutations, le spectre d'un certain corps conservera toujours son caractère individuel." [1]

Ångström did not object merely on theoretical grounds. He saw, or thought he saw, room to ascribe all these fluted spectra to impurities.

He was strengthened in this view by observing how, in the case of the spectra of known compounds, there were always flutings in one part of the spectrum or another; a rapid induction naturally, therefore, ascribed all flutings to compounds. The continuity of the gaseous and liquid states of matter, let alone the continuity of Nature's processes generally, never entered into the question. For Ångström, as for the modern chemist, there was no such thing as evolution, no possibility of a close physical relationship between elements, so called, driven to incandescence from the solid state, and binary compounds of those elements.

[1] Ångström sur "Le Spectre normal du Soleil," page 39.

In a memoir, however, which appeared after Ångström's death, and which, though under a different title, was in all probability the one referred to, this opinion was to a large extent recalled, and in favour of Plucker's view, in the following words:—

". . . Nous ne nions certainement pas qu'un corps simple ne puisse dans certains cas donner différents spectres. Citons, par exemple, le spectre d'absorption d'iode que ne ressemble en aucune façon au système des raies brillantes du même corps, obtenues au moyen de l'électricité; et remarquons de plus qu'en général tout corps simple, presentant la propriété d'allotropie, doit donner à l'état d'incandescence des spectres différents, pourvu que la dite propriété de la substance subsiste non seulement à l'état gazeux du corps, mais encore à la température même de l'incandescence. . . .

"Le soufre solid possède, somme on sait, plusieurs états allotropiques, et, d'après certaines observations, ce corps, même à son état gazeux, prendrait des formes différentes. Par conséquent, en supposant que cela soit vrai, le soufre gazeux doit donner plusieurs spectres d'absorptio, tandis que la possibilité d'un seul on de plusieurs spectres brillants dépendra de la circonstance suivante, savoir si les états allotropiques plus complexes de cette substance supporteront la température de l'incandescence, avant de se décomposer.

"Il est bien évident que les cas dont nous venons de parler, ne forment pas une exception à la loi générale énoncée ci-dessus, savoir que chaque corps simple ne peut donner qu'un seul spectre. En effet, si l'on suppose que l'état allotropique est dû à la constitution moléculaire du corps, soit que les molécules se combinent les unes avec les autres, soit qu'elles s'arrangent entre elles d'une certaine manière, cet état allotropique possèdera au point de vue spectroscopique, toutes les propriétés significatives d'un corps composé, et par conséquent il doit être décomposé de la même façon que celui-ci par les effets de la décharge disruptive de l'électricité." [1]

I say that in this paper Ångström recalled his own in favour of Plucker's view, because (as it has been remarked by Dr. Schuster [2]) the word "element" is used in a special sense—because in reality allotropic states are classed as compounds, that particular allotropic state which is to be regarded as truly elemental not being stated, nor any reason given why one should be thus singled out.

In the letter to which I have just referred Dr. Schuster gives an instance in which in order to show that elementary bodies did not really possess two spectra, a double spectrum was assigned to an acknowledged compound; the fluted spectra of hydrogen and carbon which differ from each other as widely as fluted spectra can, being both ascribed to acetylene.

Salet in his admirable work on the Spectra of the Metalloids,[3] was driven to the conclusion that many of these bodies must be held to possess two spectra. His conclusions are thus expressed:—

"Nous avons comparé le spectre d'absorption du brome et de l'iode à leur spectre électrique, et cette comparaison nous semble mettre hors de doute la possibilité des spectres doubles. . . .

"Nous avons obtenu, par voie électrique, un spectre primaire de l'iode correspondant à son spectre d'absorption. Le soufre, le sélénium et le tellure nous ont offert des spectres de combustion très-analogues aux spectres primaire obtenus par voie électrique, mais différant essentiellement des spectres des lignes. . . .

[1] Ångström and Thalén's "Recherches sur les Spectres des Métalloïdes," p. 5.
[2] NATURE, vol. xv. p. 447.
[3] *Ann. de Chimie et de Physique*, 1873, vol. xxviii. p. 1.

"Nous avons produit le spectre primaire de l'azote avec différents corps qui n'ont absolument de commun que l'azote; nous pensons donc avoir démontré qu'il appartient bien réellement à ce métalloïde." (*Annales de Chemie et de Physique*, 4 série, tome xxviii. pp. 70, 71).

In 1868 Wullner[1] gave his attention to this subject, and strongly supported Plucker's view of the existence of double spectra, indicating at the same time that the difference of temperature must be regarded as the sole cause of the phenomenon, adding, however, "a decomposition with further elements is not to be thought of." In the case of hydrogen he showed that the banded spectrum ascribed to acetylene really depended upon a change in the emissive power brought about by an alteration of temperature. Touching oxygen, he showed that three distinct spectra may be obtained, while in nitrogen two are observed.

I may say that in my early laboratory experiments I was at first led to think that, in the case of metallic vapours, Ångström's first expressed opinion was correct, and I said so. But after more experience and knowledge had been acquired, I was compelled by the stern logic of facts to abandon it, and I showed, first, that more "orders" of spectra—to use Plucker's term—were necessary, and then that the line spectrum itself was in all probability compound; that is, that it was in some cases built up by the vibration of dissimilar molecules, some of which might even give us a fluted spectrum, if we could study them alone.

Although, however, in the views I have expressed on former occasions I have had the advantage of the support of the opinion of Plucker and Ångström, and later of Dr. Schuster,[2] not to mention others, I am aware that though there is a general consensus among spectroscopic workers that double spectra cannot be ascribed to impurities, it is not absolute.

I propose therefore in this place to refer to a special case in which this question has been recently brought prominently forward.

I have already stated that Ångström, who was the first to map the line-spectrum of carbon, ascribed the flutings ordinarily seen in the carbon compounds to acetylene.

Now Attfield, in 1862, as a result of a most carefully conducted and admirably-planned set of experiments, came to the conclusion that the flutings were really due to carbon: in short, that carbon, like hydrogen, iodine, sulphur, nitrogen, and other bodies, had a fluted spectrum as well as one consisting wholly of lines.

The work of Attfield will be gathered from the following extract from his paper (*Phil. Trans.*, vol. clii. part 1, p. 221 *et seq.*):—

"On recently reading Swan's paper by the light that Professors Bunsen and Kirchhoff have thrown on the subject, I came to the conclusion that these bands must be due to incandescent carbon vapour; that, if so, they must be absent from flames in which carbon is absent, and present in flames in which carbon is present; that they must be observable equally in the flames of the oxide, sulphide, and nitride as in that of the hydride of carbon; and, finally, that they must be present whether the incandescence be produced by the chemical force, as in burning jets of the gases in the open air, or by the electric force, as when hermetically-sealed tubes of the gases are exposed to the discharge of a powerful induction-coil. . . .

"To establish the absolute identity of the hydro- and nitro-carbon spectra, excluding of course the lines due to nitrogen, they were simultaneously brought into the field of the spectroscope: one occupying the upper, and the other the lower half of the field.

"This was readily effected after fixing the small prism, usually supplied with spectroscopes, over half of the narrow slit at the further end of the object-tube of the instrument. The light from the oxyhydrocarbon flame was now directed up the axis of the tube by reflection from the little prism, while that from the oxynitrocarbon flame passed directly through the uncovered half of the slit. A glance through the eye-tube was sufficient to show that the characteristic lines of the hydrocarbon spectrum were perfectly continued in the nitrocarbon spectrum. A similar arrangement of apparatus, in which the hydrocarbon light was replaced by that of pure nitrogen, showed that the remaining lines of the nitrocarbon spectrum were identical with those of the nitrogen spectrum. In this last experiment the source of the pure nitrogen light was the electric discharge through the rarefied gas.

"The above experiment certainly seemed to go far towards proving the spectrum in question to be that of the element carbon. Nevertheless, the ignition of the gases having been effected in air, it was conceivable that hydrogen, nitrogen, or oxygen had influenced the phenomena. To eliminate this possible source of error, the experiments were repeated out of contact with air. A thin glass tube 1 inch in diameter and 3 inches long, with platinum wires fused into its sides, and its ends prolonged by glass quills having a capillary bore, was filled with pure dry cyanogen, and the greater portion of this gas then removed by a good air-pump. Another tube was similarly prepared with olefiant gas. The platinum wires in these tubes were then so connected with each other that the electric discharge from a powerful induction-coil could pass through both at the same time. On now observing the spectra of these two lights in the simultaneous manner previously described, the characteristic lines of the hydrocarbon spectrum were found to be rigidly continued in that of the nitrocarbon. Moreover, by the same method of simultaneous observation, the spectrum of each of these electric flames, as they may be termed, was compared with the corresponding chemical flames, that is, with the oxyhydrocarbon and oxynitrocarbon jets of gas burning in air. The characteristic lines were present in every case. Lastly, by similar inter-observation a few other lines in the electric spectrum of the hydrocarbon were proved to be due to the presence of hydrogen, and several others in the electric spectrum of the nitrocarbon to be caused by the presence of nitrogen. . . ."

"The spectrum under investigation having then been obtained in one case when only carbon and hydrogen were present, and in another when all elements but carbon and nitrogen were absent, furnishes, to my mind, sufficient evidence that the spectrum is that of carbon."

"But an interesting confirmation of the conclusion just stated is found in the fact that the same spectrum is obtained when no other elements but carbon and oxygen are present, and also when carbon and sulphur are the

[1] *Phil. Mag.*, sec. 4, vol. xxxvii. p. 405.

[2] Dr. Schuster's recently published investigations are as follows:—

Mr. Lockyer's investigations have shown that most bodies give us a continuous spectrum, as a gas, before they condense, and many at a considerable temperature above the boiling point. *Mr. Lockyer has rightly drawn the conclusion from these facts, that the atomic aggregation of the molecules is the cause of the different orders of spectra.*

That the discontinuous spectra of different orders (line and band spectra) are due to different molecular combination, I consider to be pretty well established, and analogy has led me (and Mr. Lockyer before me) to explain the continuous spectra by the same cause; for the change of the continuous spectrum to the line or band-spectrum takes place in exactly the same way as the change of spectra of different orders into each other. Analogy is not a strong guide, yet some weight may be given to it in a case like the one under discussion, where experiment hitherto has failed to give a decided answer. (Dr. A. Schuster on the Spectra of Metalloids, *Phil. Trans.* Royal Society, 1879. Part i page 38 and 89, note.)

only elements under examination. And first with regard to carbon and oxygen. Carbonic oxide burned in air gives a flame possessing a continuous spectrum. A mixture of carbonic oxide and oxygen burned from a platinum-tipped safety-jet also gives a more or less continuous spectrum, but the light of the spectrum has a tendency to group itself in ill-defined ridges. Carbonic oxide, however, ignited by the electric discharge in a semi-vacuous tube, gives a bright sharp spectrum. This spectrum was proved, by the simultaneous method of observation, to be that of carbon plus the spectrum of oxygen. With regard to carbon and sulphur almost the same remarks may be made. Bisulphide of carbon vapour burns in air with a bluish flame. Its spectrum is continuous. Mixed with oxygen and burned at the safety-jet, its flame still gives a continuous spectrum, though more distinctly furrowed than in the case of carbonic oxide; but when ignited by the electric current its spectrum is well defined, and is that of carbon plus the sulphur. That is to say, it is the spectrum of carbon plus the spectrum that is obtained from vapour of sulphur when ignited by the electric discharge in an otherwise vacuous tube."

"Having thus demonstrated that dissimilar compounds containing carbon emit, when sufficiently ignited, similar rays of light, I come to the conclusion that those rays are characteristic of ignited carbon vapour, and that the phenomena they give rise to on being refracted by a prism is the spectrum of carbon."

This question was next taken up by Morren. He wrote[1] (in 1865) fifteen years ago:—

"A la réception de cet intéressant et substantiel Mémoire, j'avoue que je ne regardai pas d'abord comme fondée l'assertion de M. Attfield. . . .

"Je me suis donc mis au travail avec la pensée préconçue de combattre l'assertion émise par le savant anglais; mais pas du tout, il résulte au contraire des expériences auxquelles je me suis livré que M. Attfield a raison, et que c'est bien la vapeur du carbone qui donne le spectre indiqué plus haut. . . .

"Si on fait brûler le cyanogène au moyen du chalumeau à deux courants, en faisant arriver au centre de la flamme du cyanogène un courant d'oxygène très-pur (cette condition est indispensable), on voit se produire un des plus beaux effets de combustion possible, et cette expérience est certainement une des plus magnifiques qu'on puisse réaliser sur la combustion des gaz. Il se produit, au milieu de la flamme *rosé-violâtre* du cyanogène, une boule d'un blanc vert éboulissant qui rappelle la lumière électrique produite par le courant de la pile entre deux charbons de cornue. Si le spectroscope est dirigé sur cette brillante lumière, on aperçoit, avec une splendeur merveilleuse, le même spectre de la partie bleue des flammes hydrocarburées. Ainsi donc c'est du charbon seul, mais à l'état de vapeur, qui forme cette boule brillante qui plus loin, par son union avec l'oxygène, va passer à l'état d'acid carbonique. Du reste ce spectre n'est pas seul; avec lui on voit, mais très-effacé, le spectre spécial du cyanogène, et celui-ci tend de plus en plus à disparaître à mesure que l'oxygène arrive avec plus d'abondance et brûle de mieux en mieux le cyanogène. Quant au spectre de l'azote, on ne l'aperçoit pas dans cette vive lumière. Le magnifique éclat de ce beau spectre, le plus beau qu'il m'ait été donné de voir, permet de bien comprendre l'aspect creusé et ombré avec une teinte croissante qu'on remarque dans les parties qui n'ont pas de raies brillantes, et même entre ces raies."

Four years later Dr. Watts devoted himself to this subject, and in 1869 his work was thus summarised by himself:[2]—

[1] *Annales de Chimie et de Physique*, 4 série, tome iv. p. 309, 312.
[2] *Phil. Mag.*, October, 1869.

"This spectrum [that consisting of the flutings in question] may be obtained from the flame of any hydrocarbon, though in many cases, owing to the faintness of the spectrum, only some of the groups can be recognised. In the flame of an ordinary Bunsen burner δ and ϵ are easily seen, γ and f are much fainter, and the red group cannot be detected.

"This spectrum is proved to be that of carbon, inasmuch as it can be obtained alike from compounds of carbon with *hydrogen*, with *nitrogen*, with *oxygen*, with *sulphur*, and with *chlorine*. I have obtained it, namely, from each of the following compounds:—olefiant gas, cyanogen, carbonic oxide, naphthalin, carbonic disulphide, carbonic tetrachloride, amylic alcohol, and marsh-gas."

That these conclusions, successively arrived at by Attfield, Morren, and Watts, are sound, I shall show in my next notice. J. NORMAN LOCKYER

(*To be continued.*)

SCIENCE IN PARLIAMENT

THE House of Commons is now complete; all the boroughs and counties have made their choice, and the composition of the new Parliament has been and will be criticised from many points of view. So far as the interests of science and of what we conceive to be good education are concerned, there is, we fear, little difference between the present House of Commons and its predecessor; just a thin ray of light athwart a cloud of darkness, a tiny morsel of knowledge in a mass of ignorance. This ignorance, however, we are bound to believe is not wilful; we must admit that our new rulers are willing to be enlightened, unless in time they should show themselves otherwise disposed.

On this ground, as well as on others, it is to be lamented that one of the most eminent and useful scientific members of the House has lost his seat through some local caprice. The absence of Sir John Lubbock from the new Parliament is one we are sure every true lover of science will deplore. Where there is so much ignorance to be overcome, it seems to us we cannot have too many representatives of science in Parliament; and we are sure all who desire to see science advanced in this country would welcome any chance of getting Sir John back to his old place. Such an opportunity has, some may think almost providentially, presented itself in the vacancy that has occurred in the representation of London University by the promotion of Mr. Lowe to "another place." Several candidates have been proposed for the vacant seat, but alongside of Sir John Lubbock all must strike an impartial onlooker as singularly unsuitable. The "doctors" have been attempting to put in a strong claim to have themselves specially represented, supporting their cause, so far as London University is concerned, by somewhat shaky statistics. But medicine has no lack of friends in both Houses of Parliament; the claims which it has on the country are patent to all, and it is, moreover, included under the wider region of science. If the latter gets fair play from Government, medicine need have no fear that her claims will be neglected. Already are two Scottish universities represented by Dr. Lyon Playfair, who is nothing if not medical. Not one of our English universities has a man of science as its representative, and it is surely important that an institution in which science holds so prominent

a place as London University should have a scientific man for its representative. Sir George Jessel has for some reason a few strenuous advocates, who seem to forget that their candidate resigned his seat for Dover on the ground that it was contrary to the spirit of the act. Sir George is an excellent lawyer, but there are already too many of them in Parliament. Sir John Lubbock has already been fourteen years member of the Senate, and nearly eight vice-chancellor; thus by returning him not only would the London University confer a benefit on Parliament and the country at large, but at the same time would do the best they could for their own interests. We need not here insist on the claims of Sir John as a man of science; his eminence in this department, as well as a man of business is, known to all. He is indeed so many-sided that he would represent as few others could the different faculties which combine to form the London University. His career in Parliament has been marked by a large number of measures which he has carried through Parliament, all of them of a kind more or less affecting the alumni of London University, and several of them directly affecting those very medical men that would now turn their backs upon him. Sir John has been officially connected with various bodies and various movements having for their object the promotion of learning and science, and now we believe he has had the great honour of being designated as President of the British Association for its jubilee meeting at York next year. We should have thought that for a body like the members of London University it would have been unnecessary to point out Sir John Lubbock's claims upon them, and his peculiar fitness to represent them in Parliament. We are confident that all the scientific members of the institution will record their votes in his favour, and by sending him to Parliament strengthen the hands of the few who are intelligently convinced of the necessity of introducing and carrying out those reforms which are so much needed in the attitude of Government towards science and education.

WURTZ'S "CHEMISTRY"

Elements of Modern Chemistry. By Adolphe Wurtz. Translated and edited by Wm. H. Greene, M.D. (London: W. Swan Sonnenschein and Allen, 1880.)

M. WURTZ is one of the recognised leaders of modern chemistry: a text-book from his pen is sure to be hailed with interest and pleasure.

The reputation of the author as an original thinker and worker in chemical science leads one to look for something more than the ordinary orthodox collection of oft-repeated facts in any work bearing his name. And the opening pages of the book before us are certainly very refreshing. Simple and commonly-occurring facts are clearly and simply stated, and on these, as a basis, is aid at once the foundation of chemical theory.

The leading features of the book are, clearness of statement, selection of typical facts from among the vast array at the service of the chemical compiler, and devotion of a comparatively large space to chemical theory and to generalisations which are usually dismissed in a few words in the ordinary text-book.

Perhaps the most remarkable feature of M. Wurtz's book is that, notwithstanding that within less than 700 moderate-sized pages there is given an account of the leading properties of all the more important substances known to chemistry, the book is nevertheless exceedingly interesting and eminently readable. Probably this result could only be attained by a French writer.

In a very early part of the book the modern theory of valency or equivalency is explained, and this theory pervades the whole of the work. The great objection to the book, considered as an exponent of modern chemistry, in our opinion, is this marked devotion to one favourite theory. The objection which we should make to the book, considered more broadly as a scientific treatise, is that theoretical considerations are too much treated as identical with facts, and that facts are, seemingly, supposed to be explained when they are only stated in the language of that peculiar theory which finds in such expressions as "exchange of affinities," "satisfaction of bonds," &c., an *explanation* of chemical phenomena. The theory of valency assumes that the molecular weights of those compounds which are employed in determinations of valency are known. But at present we know the molecular weights of gasifiable bodies only; hence no exact conclusions concerning valencies can be drawn from a study of non-gasifiable compounds. Nevertheless M. Wurtz appears to regard the formulæ of many non-volatile metallic oxides as on an equal footing with those of such compounds as water, hydrochloric acid, &c., and as just as serviceable for determinations of elementary valencies.

Indeed we do not find given a clear definition of molecular weight as distinguished from atomic weight. Avogadro's hypothesis, it is true, is mentioned, but not clearly stated as the basis of the modern system of molecular weight determinations. And without a definition of molecular weight, clearly established, it is impossible to grasp the modern acceptation of the term atomic weight.

In such a work as this one might reasonably look for a statement of the results of the recent work, of first-rate importance, of Guldberg and Waage, and of Ostwald, on Chemical Affinity, more especially as the subject of mass action is mentioned and Berthollet's laws are detailed.

The general subject of affinity is somewhat vaguely treated. Thermal chemistry scarcely finds any recognition in the work.

It may seem invidious to mention faults of detail; but there are a few which, we think, might very profitably be corrected in a second edition.

The nomenclature of the oxyacids of sulphur is certainly erroneous: hyposulphurous acid—H_2SO_2—is called hydrosulphurous, and thiosulphuric—$H_2S_2O_3$—hyposulphurous. The nomenclature of the oxides of iodine is also peculiar, and the formulæ of the known oxides are somewhat startling: perbromic acid is still enumerated among the oxyacids of bromine. Dry sulphuretted hydrogen is said to be energetically decomposed by iodine. SO_2 is called sulphurous oxide *or* sulphurous acid gas; and, lastly, Lavoisier is said to have determined the composition of water in 1785.

That part of the book which deals with the carbon compounds is not so satisfactory as the portion treating of inorganic chemistry. The classification is most unnatural, and the treatment of many important groups, *e.g.*, the alcohols and terpenes, is unsatisfactory.

We should not think it possible for an average student

of chemistry, beginning the study of the carbon compounds with the aid of this manual, to gain any but most hazy ideas regarding the general scope of this branch of the science.

But notwithstanding such defects as those we have mentioned there can be little doubt that M. Wurtz's book is possessed of many admirable qualities. In place of masses of unconnected facts he presents the student with carefully-selected leading data; he may, we think, strain some of his favourite theories too much, yet he inculcates the paramount necessity of theoretical explanations; he gives prominence to generalisations, such as equivalents, combining weights, and laws of multiple proportions, nomenclature and notation, bases, acids, and salts, &c., &c., and these he develops historically with great clearness and rare felicity of illustration; and he gives just sufficient detail concerning chemical manufactures as suffices to render these intelligible to the ordinary student of chemistry.

The translation appears to be admirably executed. The book is well printed, and the illustrations are distinct. But why should one be led to believe that spirit-lamps and charcoal-furnaces are still the ordinary appliances for raising the temperature of substances in chemical laboratories?

In reading the historical notes which are given concerning most of the important compounds and generalisations of chemistry, one is almost persuaded to believe that, after all, "chemistry is a French science."

M. M. P. M.

OUR BOOK SHELF

The Geological Antiquity of Insects. Twelve Papers on Fossil Entomology. By Herbert Goss, F.L.S. 8vo, pp. 1-50. (London: John Van Voorst, 1880.)

THIS bulky pamphlet must prove decidedly useful both to geologists and entomologists. The subject of fossil entomology has of late assumed gigantic proportions, and asserted an importance little dreamt of when palæontology first substantiated its claims as the real guide to geologists in determining the nature of many strata. Indeed, as is truly stated by Mr. Goss, the wonder is that remains of any animals so fragile as insects could have been preserved sufficiently for scientific purposes; yet we find contemporaneous with the remains of those marvellous Devonian fishes those of the earliest types of insects, chiefly only wings, it is true, but wings in such a complete state of preservation that the intricacies of neuration can be traced; and this neuration is in some cases so difficult to homologise with that of existing forms that a separate, supposed extinct order (*Palæodictyoptera*) has been formed (probably unnecessarily) for the reception of these remains. Mr. Goss has given detailed accounts (with copious references) of almost every described species of fossil insect from the older formations, and has contrived to very lucidly place before his readers the sequence of appearance of the now-existing orders according to the testimony of the rocks. As we ascend in the geological scale the indications become less complete, and only genera, or eventually only families, are alluded to, but always with the same copious references to authorities. It could not be otherwise. As we ascend the materials increase enormously, until at last, in the post-tertiary system, we find ourselves in the presence of remains that have been identified with species now living in the same district; and in somewhat less recent strata in North America the multitude of fossil remains of insects is such as to place it out of the question that any detailed account could be given of them. Not the least useful feature in the work consists in the notes on the correlation of special insect-forms with the most remarkable animal and vegetable relics from the same formations.

This pamphlet has no claims as embodying the results of original research; it is a useful concentrated compilation from the literature on the subject by one who evidently has an intelligent knowledge of it both in its geological and zoological aspects, and as such cannot fail to be of service as a text-book, giving the student a clear outline sketch, and the references where to seek more detailed information. Such a work is often more useful than original essays, which, from the magnitude of the subject, can only be limited in their aim. The treatment may be a little unequal, and we think it would be possible to point out cases in which certain fossil-insects have been referred to a wrong position; but this is the fault of the original describers.

We are rather sorry to see that all notice of Amber-Insects is intentionally omitted for the present, more especially as, from the medium in which they are preserved, these are the most perfect of all fossil insect-remains. They consist for the most part of well-marked existing genera, but we think no one has yet dared to identify any amber-insect with an existing species. In connection with this subject one word of caution to palæontologists with regard to many fossil insects. We find many insects (excluding those in amber) referred to modern genera, and even among those from ancient strata. This is a convenience only; it indicates that certain fossils present the general appearance of the existing genera to which they are referred; but in the majority of instances it does not prove that they would be so referred if the remains were in the same condition as the recent materials. In most cases we think it would be otherwise.

The substance of this pamphlet originally appeared as a series of introductory papers in vols. xv. and xvi. of the *Entomologists' Monthly Magazine*, but the reprint contains additional matter.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Opportunities of Science Masters at Schools

IN consequence of my publishing in your columns some facts on visual and other memory, I have been favoured with letters from many persons and from many countries; few however have been more acceptable than those from the masters and mistresses of schools. Confining my remarks for the present to the masters of the larger establishments, I may mention that the science masters of Cheltenham and of Winchester have promised assistance, but I write especially to acknowledge the aid already rendered to me by Mr. W. H. Poole, the science master of Charterhouse, and to make some comments thereon, in order to show how wide and yet how neglected a field for original research lies open to every schoolmaster. Mr. Poole has sent me returns from all the boys who attended his classes—172 in number. He selected certain of my questions concerning visual and other memory, he explained them clearly to the boys and interested them in the subject, and then he set them the questions to answer in writing, just as he would have set questions in the ordinary course of school-work. Lastly, he forwarded to me the replies in separate bundles corresponding to the different classes, and each paper was numbered, so that if I wanted to learn more about any of them and sent him the numbers, he

could ascertain the names of the writers. In this simple manner, by almost a single stroke, Mr. Poole has called a mass of statistical data into existence, more thorough and complete than could perhaps have been procured in any other way. I have spent many hours in analysing the answers, and find that they bear generally the marks of painstaking and veracity; they have already led me to results which appear important, but of which this is not the time to speak.

The observation I desire to make is that as every hospital fulfils two purposes, the primary one of relieving the sick, and the secondary one of advancing pathology, so every school might be made not only to fulfil the primary purpose of educating boys, but also that of advancing many branches of anthropology. The object of schools should be not only to educate, but also to promote directly and indirectly the science of education.

It is astonishing how little has been done by the schoolmasters of our great public schools in this direction, notwithstanding their enviable opportunities. I know absolutely of no work written by one of them in which his experiences are classified in the same scientific spirit as hospital cases are by a physician, or as other facts are by the scientific man in whose special line of inquiry they lie. Yet the routine of school work is a daily course of examination. There, if anywhere, the art of putting questions and the practice of answering them is developed to its highest known perfection. In no other place are persons so incessantly and for so long a time under close inspection. Nowhere else are the conditions of antecedents, age, and present occupation so alike as in the boys of the same form. Schools are almost ideally perfect places for statistical inquiries. If a census on other subjects such as this that has been made by Mr. Poole, was carried out, say once a term, or even once a year, at each great public school, what a rich statistical output we should annually witness. Or again, if a schoolmaster were now and then found capable and willing to codify in a scientific manner his large experiences of boys, to compare their various moral and intellectual qualities, to classify their natural temperaments, and generally to describe them as a naturalist would describe the fauna of some new land, what excellent psychological work might be accomplished! But all these great opportunities lie neglected. The masters come and go, their experiences are lost, or almost so, and the incidents on which they were founded are forgotten, instead of being stored and rendered accessible to their successors; thus our great schools are like mediæval hospitals, where case-taking was unknown, where pathological collections were never dreamt of, and where in consequence the art of healing made slow and uncertain advance.

Some schoolmaster may put the inquiry, What are the subjects fitted for investigation in schools? I can only reply, Take any book that bears on psychology, select any subject concerning the intellect, emotions, or senses in which you may feel an interest; think how a knowledge of it might best be advanced either by statistical questioning or by any other kind of observation, consult with others, plan carefully a mode of procedure that shall be as simple as the case admits, then take the inquiry in hand and carry it through.

FRANCIS GALTON

Museum Conference

PRESUMING that the object of a museum is twofold, viz., to instruct the general public through the eye and to serve as a repository of material by means of which specialists can carry on their scientific and historical researches, it must be obvious to every thoughtful observer how inadequate the machinery generally is to the end in view. A visitor, let us suppose, to the zoological department of a museum, observes a number of birds bearing a general family likeness, and a name under each specimen. Having no pictorial clue to the habits, native country, or specific distinctions of the numerous specimens, no verbal description before him, and no intelligent curator on the spot to give the information required, he goes away with a hazy impression of what he has seen, and too often with a headache. Surely there is room for improvement in the direction of the amount of information that could be conveyed by proper adjuncts to the specimens, and by grouping them according to the countries to which they belong, &c.? Many a missionary going abroad would gladly learn something of the economical and medicinal products of the country to which he is going; but in a museum in which vegetable products are grouped according to their natural orders his difficulties are increased tenfold. I can imagine no better means of improving the character of museums and of increasing their usefulness than a conference of curators to exchange ideas and the results of their experience. With regard to the use of musems by those seeking special information, the circumstances are very different in large cities and in small towns. In cities, as a rule, the curator naturally becomes in time the depository of a large amount of special information, for which there is such a demand that time is rarely left him for the manual labour and supervision which the keeping of a museum in good order involves. In this case it is assistance that is required rather than increase of salary, although a curator should in my opinion be so well paid that he need not be obliged to resort to literary work to eke out a living.

In provincial towns the case is somewhat different. The curator has less demand made upon his time by specialists, but he needs to be well acquainted with almost every branch of art and natural history, and is often expected to be able to lecture upon any subject that can at all be included within the range of objects in the museum. Such extensive knowledge is rarely to be found concentrated in one person, and consequently one branch of natural history is often pursued to the exclusion of others, as of arts and antiquities, or *vice versâ*; and it is little consolation to the naturalist who has done good local work to think that if his collection be left to the local museum it may become devoured by insects or neglected by a subsequent curator who takes little or no interest in that particular branch.

A monthly or quarterly publication would form an excellent means of communication for the exchange of duplicates, the distribution to suitable quarters of the productions of foreign countries for purposes of investigation, for the record of improvements in manipulation or exhibition, and for the results of experience in various directions. Such a publication, if circulated abroad, might be made the means of incalculable benefit to trade by suggesting uses for little known native productions and by bringing residents abroad in communication with those at home who could direct them how best to utilise the resources of newly-explored districts.

I see no reason also why museums, especially those of a technical character, should not be made in some degree self-supporting, by charging a small admission fee to visitors and a fixed fee for the identification of objects used or to be used in trade. I trust the subject of a museum conference will be well ventilated in your columns, and that the liberal offer of the Council of the Society of Arts will soon be turned to account by a preliminary meeting in the rooms of that Society. I would suggest that those who are able and willing to form an executive committee should forward their names at once to Mr. Paton, who will then be in a position to carry out a scheme which cannot fail to produce a beneficial effect upon the education of the nation at large.

E. M. HOLMES

Ural Crayfish

REFERRING to the notice in NATURE, vol. xxi. p. 454, of M. Malakhoff's memoir on Ural Crayfish, you will perhaps allow me, a resident among the foot-hills of the South-Western Urals, space for a few words. *Astacus leptodactylus* is found in most of the streams here, in some abundantly. The variety is that in which the cephalo-thorax and chelæ are studded with tubercles, and is accurately represented in Prof. E. Ray Lankester's Fig. 2, in NATURE, vol. xxi. p. 354. I have one before me at the present moment from a tributary of the River Bielaia, measuring five inches in length, and this is the average size. I have never seen the mountain variety mentioned in M. Malakhoff's paper. His remark that "in the Ural the natives call the freshwater Unio *Rak* (*Ecrevisse*) and the true crayfish *Rak-ryba* (*l'Ecrevisse poisson*)" does not apply to this district, for here the latter is called simply "*rak*" and the unio "rakovitza" and "rakovina" indifferently, general terms for a mullusc and its shell. Various opinions exist in reference to the quality of the flesh. For my own part I find it extremely insipid, and I believe any Englishman eating it for the first time would be of the same opinion; but the inhabitants of the country, who have, of course, no opportunity of tasting fresh marine crustacea, rather esteem the flesh. Englishmen staying here a long time often grow to like it in default of anything better, till I verily believe in some cases they leave the country praising it as a delicacy. This may be one of the ways in which the diverging opinions respecting its quality have originated.

W. H. TWELVETREES

Voskresensky Zavod, near Orenburg, Russia,
March 27 (April 8)

Protection against Mosquitos, Flies, and Blight

MR. HAGEN's letter on the destruction of insect-pests (NATURE, vol. xxi. p. 611) induces me to make generally known an absolute preventive of the bites of mosquitos, gnats, of green-fly in the vinery, blight in the garden, and a protection to animals from these "insect-pests." A few years ago I had some peach-trees which, being on a wall exposed to draught, were annually blighted. One died, and the new wood of the others was not more than a hand's length. A scientific friend advised me to try a weak solution of quassia to water them with, and the success was complete. Blight was prevented. The first year the trees bore well and the new wood was elbow-length or more. I next tried quassia in the vinery. Instead of lime-washing the walls to get rid of the green-fly, one watering with quassia dismissed them in a day. My head-gardener, who had previously much experience in nursery-grounds, wondered that he had never heard of it before. He now uses it in all cases as a protection from flies and blight. The dilution goes a long way: one pound of chips of quassia-wood boiled and reboiled in other water until he has eight gallons of the extract for his garden-engine. He finds it inadvisable to use it stronger for some plants. This boiling makes the quassia adhesive, and being principally applied to the underleaf, because most blight settles there, it is not readily washed off by rain. Quassia is used in medicine as a powerful tonic, and the chips are sold by chemists at from sixpence to a shilling a pound. The tree is indigenous to the West Indies and to South America.

And now as to gnats and mosquitos. A young friend of mine, severely bitten by mosquitos and unwilling to be seen so disfigured, sent for quassia-chips and had boiling water poured upon them. At night, after washing, she dipped her hands into the quassia water and left it to dry on her face. This was a perfect protection, and continued to be so whenever applied. The pastilles sold in Florence and elsewhere, which are vaunted to be safeguards against mosquitos, are, from my own experience, of no use.

At the approach of winter, when flies and gnats get into houses and sometimes bite venomously, a grandchild of mine, eighteen months old, was thus attacked. I gave the nurse some of my weak solution of quassia to be left to dry on his face, and he was not bitten again. It is innocuous to children, and it may be a protection also against bed insects, which I have not had the opportunity of trying. When the solution of quassia is strong it is well known to be an active fly-poison, and is mixed with sugar to attract flies, but this is not strong enough to kill at once. If it be true that mosquitos have been imported into one of the great hotels in the south-west of London, it might be very useful to anoint some of the furniture with it. Then a strong solution with sugar set about the rooms ought to clear them out.

Oatlands Park, Weybridge WM. CHAPPELL

Immersion of Iron and Steel in Acidulated Water

IN NATURE, vol. xxi. p. 602, I have read an interesting account of Prof. Hughes's experiments on the change produced in iron and steel wire by immersion in acidulated water.

May I ask you to draw the Professor's attention to my experiments on this subject, *vide Proceedings* of the Literary and Philosophical Society of Manchester, January 7, March 4, December 30, 1873; January 13, March 10 and 24, 1874; and *Proceedings* of the Royal Society, No. 158, 1875; and a short article in NATURE, I think.

It has long been known to manufacturers of iron wire that iron becomes brittle after immersion in dilute sulphuric or hydrochloric acids. I believe, however, that I was the first to show that this change was due to occluded hydrogen, and by a careful series of experiments to determine approximately the percentage alteration in the breaking strain and elongation at the moment of rupture produced by occluded hydrogen in—

(*a*) Ordinary or puddled iron wire;
(*b*) Iron wire manufactured with charcoal instead of coal;
(*c*) Mild or Bessemer steel;
(*d*) Cast steel.

I also found an increased electrical resistance in wire containing occluded hydrogen, though subsequent experiments have led me to believe that the numbers I first published were too large.

My papers also called attention to the diffusion of hydrogen in iron wire beyond the part immersed in acidulated water; the increase in the length of wire charged with hydrogen and some other phenomena.

The whole subject of the occlusion of hydrogen by metals is one of great interest, and the scientific world will be glad if an accomplished experimenter like Prof. Hughes turns his attention to the subject. WILLIAM H. JOHNSON

The Ferns, Bowdon, near Manchester, April 26

Stone Arrow Heads

THE interesting investigations of Mr. Redding on the method of making the above objects, as referred to in NATURE, vol. xxi. p. 613, have been somewhat anticipated by Mr. Paul Schumacher, "Methods of making stone weapons," *Bull.* U.S. Geol. and Geog. Survey, vol. iii. p. 547, 1877, which again was a translation from an earlier publication in *Archiv für Anthropologie*, vol. vii. p. 263. Mr. Schumacher's information was derived from the last arrow-maker of a tribe of Klamath Indians, and appears to correspond generally with that obtained by Mr. Redding from the representative of another tribe in the same region. Mr. Schumacher states that obsidian is not the only stone used, but chert, chalcedony, jasper, agate, and similar stones of conchoidal fracture. "The rock is first exposed to fire, and, after a thorough heating, rapidly cooled off, when it flakes readily into sherds of different sizes under well-directed blows at its cleavage." The process is also illustrated in Mr. Schumacher's paper. Superior stone mortars are often found in use amongst these Californian Indians, who deny their capability of making such objects, and account for their possession as "finds" either on the surface or beneath the earth, and describe them as the work of another and previous race.

Derwent Grove, East Dulwich, May 1

The Mode of Suckling of the Elephant Calf

IN some of the accounts recently published of the birth of an elephant in a menagerie in America it is stated that up to this time naturalists had always believed that the elephant calf obtained its mother's milk by means of its trunk, and not directly by the mouth.

Whether this be the case or not, Aristotle was certainly an exception, as the following passage from the twenty-seventh chapter of the sixth book of his "Historia Animalium" (Ed. Bekker, Oxford, 1837) clearly proves—Ὁ δὲ σκύμνος, ὅταν γένηται, θηλάζει τῷ στόματι, οὐ τῷ μυκτῆρι, καὶ βαδίζει καὶ βλέπει εὐθὺς γεννηθείς.—"And the calf, when it is born, sucks with its mouth and not with its trunk; and it both walks and sees as soon as it is born." J. C. G.

May 3

The Tay Bridge Inquiry

IN the *Pall Mall* of April 21 appeared a report of the evidence of Mr. Henry Law, C.E., in the Tay Bridge inquiry. In this report Mr. Law is made to say: "The heavy girders would fall more rapidly than the carriages; a train moving forward at a great speed would not fall so rapidly as a quiescent structure."

I have been induced to ask your insertion of this note in NATURE in the hope that some of your readers who are at home in such matters may confirm or contradict these statements. A person with a mere elementary knowledge of dynamics would disbelieve the latter of them, and would doubt that the former has any *practical* truth. Q. C.

Yeast and Black Beetles

IN what form should yeast be applied for the destruction of black beetles? If Prof. Lankester will show us how to exterminate them he will earn the gratitude of every

LONDON HOUSEHOLDER

27, Marlborough Hill, N.W., May 1

SUEZ CANAL ROCK SALT.—Dr. Ralton wishes to know where information can be obtained on the subject of the rock salt beds which were cut through in constructing the Suez Canal.

SODIC CHLORIDE CRYSTALS.—Dr. Ralton asks, what is the action of urea in modifying the crystal form of sodic chloride crystals, referred to by our reviewer of Dr. Ord's book?

[Sodium chloride usually crystallises in *cubes*; it is stated, however, by Prof. Maskelyne in a lecture before the Royal

Institution that in presence of uric acid it crystallises in *octahedra*. There are other similar facts: thus alum usually crystallises in *octahedra*; but if sulphate of alumina is present in excess the alum crystallises in *cubes*.]

THE SONGS OF BIRDS.—In Pennant's "British Zoology," vol. ii., Mr. C. C. Starling will find in an appendix a very interesting paper by the Hon. Daines Barrington on the singing of birds. The paper is dated 1773, and published in the *Philosophical Transactions*, vol. lxiii.—JAMES MACFADZEAN.

DECAISNE AND BAILLON[1]

IT is perhaps now time to make a protest against a scandal which has in no small degree excited the disgust of scientific men in various parts of Europe, who, like ourselves, have been favoured with copies of the privately-circulated publication of which the name stands at the foot of this note. That scientific men should quarrel, and quarrel sometimes with singular bitterness, is only to affirm in other terms that they are not exempt from the ordinary frailties of human nature. That they should make blunders in their work, however conscientiously performed, is but another illustration of the same truth. But that a scientific man with any respect for his calling should not merely think it worth while to publish the errors of one who has long laboured, and on the whole laboured not ingloriously, under the same roof as himself, and in the same pursuits, and should persist in the unhandsome enterprise of seeking out and raking together faults, even the most microscopic and frivolous, with all the relish and vindictiveness of gratified spite, is a thing so wholly disgusting that a protest should be made against it in the interest of common decency. Decaisne has spent a laborious life in botanical work of great usefulness and excellence, and his scientific reputation has long been established and acknowledged by his contemporaries, who have been quite capable of estimating the value of what he has done. Baillon, a much younger man, is scarcely less regarded for the industrious profusion and frequent originality of his botanical publications. But he will not materially affect the position of Decaisne by his animadversions, and it is pitiful that any portion of his abounding energy should be devoted to the attempt to discredit writings which, after all, will always be consulted by students on their own merits, and having regard to the state of knowledge at the time they were published. The fact is that no scientific man could undergo with credit such a scathing revision as that to which Baillon has subjected his unfortunate fellow-*savant*, and we do not say without some reason that the last person who would emerge from the process with anything like satisfaction would be Prof. Baillon himself.

DR. RUDOLF SCHEFFER

IT is with sincere regret that we have to record the sudden death of Dr. Rudolf H. C. C. Scheffer, the director of the Botanical Gardens, Buitenzorg, Java, which took place at Sindanglaya on March 9. The loss of Dr. Scheffer will be felt by a large circle of botanists throughout the world, for the splendid gardens of which he was superintendent were in communication with every home and colonial botanical institution; but in the Netherlands Indian Colonies, however, it is that his death will be most felt and deplored.

It is now some twelve years since Dr. Scheffer came out from Holland to take the first directorship of the gardens, which had come into high repute by the great number and variety of species collected into it by numerous eminent botanists and by the energy and zeal of its well-known *hortulanus*, J. E. Teysmann, who has by his numerous voyages added so many new species to the East Indian flora, and on the fiftieth anniversary of whose uninterrupted connection with the gardens Dr. Scheffer took so warm and active a part last January. Soon after his arrival Dr. Scheffer instituted a school for the training of native boys in the science of agriculture; and for their practical instruction he was the means of having an agricultural garden opened at Zjikoemah, close to the school, and some two miles from Buitenzorg. In this school Dr. Scheffer took the very highest interest and pleasure. It was not intended, on its institution, that he should take any active teaching duties, his superintendence was considered to be all that he could well bestow on it; but finding that the teaching staff was insufficient, he squeezed out of his already overburdened time several hours every day to devote to the tuition of these native boys. When on February 9, on his departure on a botanical journey to the south coast of Java, the writer, little thinking he was saying farewell for the last time, took leave of Dr. Scheffer, seemingly in his ordinary health, he received from him, to aid him in his work, a native boy who had lately taken his diploma of proficiency in the agricultural school. This boy was found to be well acquainted with the general flora of the district and with the classification of plants; he could accurately describe their organs and functions and state their economic uses; he had a good idea of the methods of fertilisation and the values of self- and cross-breeding. He was fairly grounded in the rudiments of zoology, anatomy, and physiology. Until he had tested this youth the writer did not believe it possible for the Malay mind to so clearly comprehend and so accurately to arrange scientific facts. In this the great power of Dr. Scheffer as a teacher appears, especially when it is remembered that he lectured almost to virgin minds and in a language so devoid of all precise and accurate terms as Malay. I am told by a friend, a competent botanist, who has listened to his lectures, that Dr. Scheffer's power of lucid explanation was very great. "I wish," he said, "I had had as good a course of lectures on botany in Holland."

In addition to the labour and anxiety attaching to this section of his work, Dr. Scheffer had also to give occasional lectures to the *aspirant controlleurs*, the young unplaced civil servants, and to superintend their examinations in agriculture. Over and above this he had the general superintendence of the large botanical gardens on his shoulders, with daily arrivals and despatches of plants *to* and *from* all quarters of the globe, on which he had to be consulted daily. If one had entered his small study in the fine building containing the herbarium, one would have found him engaged in his own peculiar work, in which he took so much delight, with his microscope and camera lucida studying the *Hemeleia vastatrix*, a subject to which he had been lately devoting much time; in another corner would be a series of Palms—part of Dr. Beccari's collection, on whose examination and description he was engaged, the sectional coloured drawings being done by one of his own native pupils. If we did not find him here we should see the microscope and pencil conveniently left so as to resume work at the shortest possible notice; and adjourning to his house, near the entrance to the gardens, we should certainly find him in his neat library surrounded by a diverse collection of botanical works, and with the spare corners decorated with the busts and photographs of distinguished botanists, with an enormous pile of correspondence, to which he was writing heads of reply in Dutch, French, English, German, for his amanuensis. Dr. Scheffer told the writer that he wrote more than 3,000 letters a year with his own hand. He corresponded with every country and every botanical garden in the world; he had to give all sorts of advice to agriculturists throughout the Archipelago, on the cultivation of or the diseases affecting coffee, tea, sugar, tobacco, &c., and the many great improvements effected in the production of these valuable products is

[1] "Errorum Decaisneanorum graviorum vel minus cognitorum centuria quinta, Auctore H. Baillon."

due in a great measure to his advice. Need we wonder, then, even with youth in his favour, that at the early age of about thirty-seven, being yoked in such heavy double harness, he has died with it on, leaving a large amount of accomplished valuable work, which was waiting for a spare moment to prepare for the publisher.

For some time Dr. Scheffer had been suffering from defective digestive powers and frequent sleeplessness, but he neglected these warnings and the advice of his friends to take some rest. He was unfortunate in being surrounded by those who, with few exceptions, took little interest in his work, and by none to whom he thought he could entrust the work in which he was so hard and enthusiastic a worker, so he worked on. The fatal affection was inflammation of the liver. The seizure was very acute, and at an early stage danger was imminent; but at length he rallied. His medical attendants considered the crisis past, and recommended his removal to his own estate near Sindanglaya, to reach which a tedious climb of 4,500 feet over the Megameudoeng Pass had to be surmounted. He never reached his destination, expiring, on March 9, at the Sanatorium at Sindanglaya, where he now lies buried.

In his private life he was a man to be loved and esteemed; quiet, unassuming, very kind-hearted, ever ready to give whatever assistance he could, especially to scientific travellers. With him the Netherlands Indian Government has lost a valued public servant, to whom it will not be easy to find a successor, and botanical science has to deplore an earnest worker, a learned disciple, and a great helper.

HENRY O. FORBES

Preanger, Java

A SCOTTISH CRANNOG[1]

BETWEEN geology and history there lies an intermediate sphere in which these sciences dovetail into one another. In this common territory or borderland lies the domain of prehistoric archæology, and to its most recent portion, or that which archæologists have designated the "Late Celtic Period," must be assigned the antiquarian remains I have here the pleasure of describing. During this period it appears that the Celtic races of Scotland and Ireland were in the habit of constructing artificial islands in marshes and shallow lakes to which, in troublous times, they resorted for safety. They were generally formed by the superposition of trunks of trees and brushwood mingled with stones strongly palisaded by stakes, and so situated as to be inaccessible except by means of causeways, or occasionally by a narrow gangway or mole. These island forts, or *crannogs*, as they have been called in the Irish annals, were very numerous in former times, but owing to the gradual rising of the level of the lakes, they appear to have been so completely lost sight of that their very existence was unknown to modern antiquaries, so that their discovery in the present century marks an important epoch in the history of archæology.

In October, 1878, I drew the attention of antiquaries, through the columns of NATURE, to the remains of an ancient lake-dwelling just then discovered on the farm of Lochlee, in the parish of Torbolton, Ayrshire. Since then a series of excavations have been made with the view of ascertaining the exact nature of this structure, in the course of which a large collection of most interesting relics has been made.

In the year 1839, while a small lake on this farm was being artificially dried up for agricultural purposes, the attention of the labourers was directed to a singular mound, in which, on cutting drains through it, they exposed some wrought wood-work; but their observations, though freely talked of in the neighbourhood at the time, led to no further results till forty years later, when it was found necessary to re-drain the locality, and hence the present investigations. By a curious coincidence the early drainage at Lochlee was made in the same year that Sir W. R. Wilde discovered and examined the first Irish crannog, viz., that of Lagore in County Meath. The Irish discovery, however, owing to a general system of drainage that was then going on, led at once to the most brilliant results, so that it soon became apparent that crannogs existed very generally over the country. Up to the present time over a hundred have been examined, and have furnished the Irish museums with a vast collection of relics. In the year 1854 a great impetus was given to the study of these researches by the discovery of the remains of ancient lake villages in Switzerland, which have now become so famous and well known all over the continent of Europe; but it was not till 1857 that the subject began to attract the attention of Scottish archæologists. In this year Mr. Joseph Robertson read a paper to the Society of Antiquaries of Scotland, and in 1866 Dr. Stuart, who was then Secretary to this Society, collected and published all the scattered notices of Scottish crannogs known up to that date. Since the publication of Dr. Stuart's elaborate paper no further investigations on Scottish crannogs, with the exception of an occasional notice of a fresh discovery of the site of one, have been recorded.

But though traces of these crannogs have been found in almost every county of Scotland, there has been no systematic examination of them worthy of comparison with the investigations that have been made in other countries; nor, with the exception of a few articles found at Dowalton, is there any collection of relics which would enable archæologists to form an opinion with much certainty as to the purpose they served in the social economy of the period they represent; nor can their range in the dim vista of prehistoric times be determined with greater accuracy.

Before the Lochlee Lake was originally drained no one appears to have surmised that a small island (visible only in the summer time) which formed a safe habitation for gulls and other sea-birds during the breeding season, was formerly the residence of man. It was situated near the outlet of the lake-basin, and the nearest land, its southern bank, was about seventy-five yards distant. The general appearance which it presented when the present investigations were commenced was that of a grassy knoll, drier, firmer, and slightly more elevated than the surrounding field. Towards the circumference of this mound the tops of a few piles were observed barely projecting above the grass. Guided by these the workmen dug a deep circular trench, in which they exposed numerous piles and transverse beams having square-cut holes in their ends, through which the former projected about eighteen inches or two feet. In the course of further explorations it became apparent that these piles formed a series of stockades surrounding a somewhat circular space about fifty feet in diameter. Beyond this circle on the south side there were indications of other rows of uprights which appeared to unite into one on the north side. Here, instead of further rows of piles, the corresponding space was occupied by an intricate arrangement of woodwork, consisting of young trees and stout branches, mixed with slanting stakes and logs running in all directions, the whole forming a dense protective barrier. The diameter of the island was about 120 feet. The central area was about three feet lower than the surrounding stockades with their transverses, and had a flooring of prepared logs resembling railway sleepers. Near the centre of this log pavement were found four circular hearths placed one above the other with an interval between each of 18 inches to $2\frac{1}{2}$ feet. These hearths were neatly constructed of flat stones of various

[1] A full report of the Lochlee Crannog is given in vol. xiii. of the *Proceedings* of the Society of Antiquaries of Scotland, and in vol. ii. of the Collections of the Ayrshire and Wigtownshire Archæological Association.

sizes, and had a raised rim round them, also formed of flat stones, but uniformly selected and set on edge. Each of them was imbedded in a thin layer of clay, which extended several feet beyond, and the intermediate strata consisted of ashes, charcoal, and small bits of burnt bones. The top of the upper hearth was 7 feet 9 inches above the log pavement, but only about one foot below the surface of the mound, so that the greatest depth of the accumulated rubbish since the log pavement was laid would be about 8½ feet. The lowest or first fireplace was separated from the log pavement by a thick layer of turf and then a layer of clay.

On a level with the third hearth, counting from below, there were decayed portions of several massive stakes, with square-cut ends which appeared to have been the remains of a hut. One stake was found to have a small portion projecting from the centre of its base, which neatly mortised into a hole formed by a piece of wood, a flat stone, and some clay, and another had pressed down the portion of clay on which it rested nearly a foot. It was thus evident that the stakes were so formed as to prevent them as much as possible from sinking by pressure. Immediately below this level, all over the area of the log-pavement, but more particularly within a circle a few feet from the fireplace, most of the relics were found. Close to this hearth, but about two feet lower, we extracted the skeleton of an animal like that of a goat or sheep, the skull of which was entire, and had short horn-cores attached to it. The relic bed was made up of partially decomposed vegetable matters, and could be separated into thin layers; the common bracken, moss, parts of the stems of coarse grass, heather, and large quantities of the broken shells of hazel-nuts were frequently met with. One of the latter was found to have a hole gnawed in it, as if made by a squirrel.

The space immediately beyond and on the south side of the log pavement, extending between it and the outer circles of piles, was occupied by a refuse heap or midden, consisting of gritty ash, decayed bones, and vegetable matters. Its breadth was ten or twelve feet, and its length from east to west nearly double that. Its surface was three feet below that of the field, so that its average depth would be about four feet. Some important relics were found here, such as metal instruments and daggers, two fibulæ, several wooden vessels, and a few bone implements. It is noteworthy that the metal objects were all comparatively near the surface of the midden, and also that no boars' tusks were found in it except at its very lowest stratum.

The probable existence of some kind of communication between the crannog and the shore of the lake was suggested at an early stage of the investigations by the discovery of a few oak piles in a drain outside the mound on its south side. Upon making excavations in the line thus indicated a very singular wooden structure was discovered, which I found no less difficult to comprehend than it now is to describe. The tops of upright stakes were first revealed, which seemed to conform to no regular arrangement, but by and by, in addition to single piles, groups of three, four, and five, here and there, were detected. The first horizontal beam was reached 7 feet below the surface of the field, which proved to be one of a complete network of similar beams lying in various directions. At a depth of 10 feet the workmen could find no more horizontal beams, and the lake silt became harder and more friable. The reason of grouping the piles now became apparent. The groups were placed in a somewhat zigzig fashion near the sides of the gangway, and from each there radiated a series of horizontal beams, the ends of which crossed each other and were kept in position by the uprights. One group was carefully inspected. The first or lowest beam was right across; the next lay lengthways, and of course at right angles to the former; then three or four spread out diagonally, like a fan, and terminated in other groups at the opposite side of the gangway; and, lastly, one again lay lengthways. Thus each beam raised the level of the general structure the exact height of its thickness, though large lozenge-shaped spaces remained in the middle quite clear of any beams. The general breadth of the portion of this unique structure examined was about 10 feet, and its thickness varied from 3 to 4 feet. A large oak plank, 10 feet long, showing the marks of a sharp cutting instrument by which it was formed, was found lying on edge at its west side and beyond the line of piles, but otherwise no remains of a platform were seen. All the beams and stakes were made of oak, and so thoroughly bound together that, though not a single joint, mortise, or pin was discovered, the whole fabric was as firm as a rock. No relics were found in any of the excavations along the line of this gangway.

The thickness, composition, and mode of structure of the island itself was ascertained by sinking a shaft at the south end of the log pavement (*i.e.*, near the centre of the island). This shaft was rectangular in form, and large enough to allow three men to work in it together. After removing the three or four layers of oak planks which constituted the log pavement, we came upon a thin layer of brushwood, and then large trunks of trees laid in regular beds or layers, each layer having its logs lying parallel to each other, but transversely and sometimes obliquely to those of the layer immediately above or below it. At the west end of the trench, after removing the first and second layers of the log pavement, we found part of a small canoe hollowed out of an oak trunk. This portion was 5 feet long, 12 inches deep, and 14 inches broad at the stern, but widened towards the broken end, where its breadth was 19 inches. This was evidently part of an old worn-out canoe, thus economised and used instead of a prepared log. Much progress in this kind of excavation was by no means an easy task, as it was necessary to keep two men constantly pumping the water which copiously flowed from all directions into the trench and even then there always remained some at the bottom. As we advanced downwards we encountered layer upon layer of the trunks of trees with the branches closely chopped off, and so soft that the spade easily cut through them. Birch was the prevailing kind of wood, but occasionally beams of oak were found, with holes at their extremities, through which pins of oak penetrated into other holes in the logs beneath. One such pin, some 3 or 4 inches in diameter, was found to pass through no less than four beams in successive layers, and to terminate ultimately in a round trunk over 13 inches in diameter. One of the oak beams was extracted entire, and measured 8 feet 3 inches in length and 10 inches in breadth, and the holes in it were 5 feet apart. Others were found to have small round projections, which evidently fitted into mortised holes in adjacent beams. Down to a depth of about 4 feet the logs were rudely split, but below this they appeared to be round rough trunks, with the bark still adhering to them. Their average diameter would be from 6 inches to 1 foot, and amongst them were some curiously gnarled stems occasionally displaying large knotty protuberances. Of course the wood in the act of digging the trench was cut up into fragments, and, on being uncovered, its tissues had a natural and even fresh-like appearance, but in a few minutes after exposure to the air they became as black as ink. Amongst the *débris* thrown up from a depth of 6 feet below the log pavement I picked up the larger portion of a broken hammer-stone or polisher, which, from the worn appearance presented by its fractured edges, must have been used subsequently to its breakage. After a long and hard day's work we reached a depth of 7 feet 4 inches, but yet there were no indications of approaching the bottom of this subaqueous fabric. However, towards the close of the second day's labour, when the probability

of total discomfiture in reaching the bottom was freely talked of, our most energetic foreman announced, after cutting through a large flat trunk 14 inches thick, that underneath this he could find no trace of further woodwork. The substance removed from below the lowest logs consisted of a few twigs of hazel brushwood, imbedded in a dark, firm, but friable, and somewhat peaty soil, which we concluded to be the silt of the lake deposited before the foundations of the crannog were laid. The depth of this solid mass of woodwork, measuring from the surface of the log pavement, was 9 feet 10 inches, or about 16 feet from the surface of the field. Amongst the very last spadefuls pitched from this depth was found nearly one-half of a well-formed and polished ring made out of shale, the external and internal diameters of which were 3½ and 2 inches respectively.

In all the trenches made at the margin and beyond the crannog the stuff dug up was of the same character and composition. First or uppermost there was a bed of fine clay rather more than 2 feet thick, and then a soft, dark substance formed of decomposed vegetable matters. The source of the latter was evident from the occurrence in its upper stratum of large quantities of leaves, stems, branches, and the roots of stunted trees apparently *in situ*. This uniformity in the composition of the silt forming the bed of the lake points to the fact that for centuries the increase was due principally to the decomposition of vegetable matters, while latterly it was caused more by a deposition of fine clay. A change so marked in the sediment can only be accounted for by a corresponding change in the surrounding scenery, and no explanation is more likely than that the primæval forests had given place to the inroads of agriculture, when some of the upturned virgin soil would be washed down, as it still is, by every trickling rill that finds its way into this lake basin.

The remains of human industry found during the excavations of the Lochlee Crannog, calculated to throw light on the civilisation and social economy of its occupiers, are very abundant. They comprise a large variety of objects, such as warlike weapons, industrial implements, and personal ornaments, made of stone, bone, horn, wood, metal, &c. In the following description of them I have adopted the principle of classification suggested by the materials of which they are composed:—

I.—*Objects made of Stone*

Hammer Stones.—A great many water-worn pebbles, of a similar character to those observed in the surrounding glacial drift and river courses, which were used as

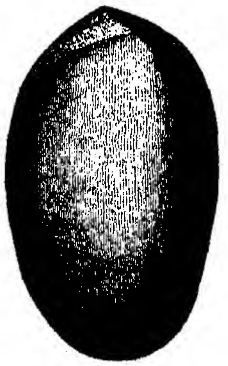

FIG. 1.—Hammer-Stone (Scale ½).

hammers, pounders, or rubbers, were found in the *débris* all over the crannog, but more abundantly in the deeper layers of a small circular area surrounding the hearths. As typical specimens of such implements I have collected no less than nineteen. Of these fourteen are of a somewhat elongated oval shape, and were used at one or both ends (Fig. 1). They vary considerably in size, the major diameter of the largest measuring 6 inches, and the rest graduating downwards to about the half of this. Two are flat and circular, and show friction markings all round, while other three were used on their flat surfaces only. One of these is divided into two portions, each of which was picked up separately, about a yard asunder, and found to fit exactly. It would thus appear that it was broken while being used on the crannog, and then pitched aside as useless.

Heating-Stones and Sling-Stones.—A large number of round stones, varying in size from half an inch to three inches in diameter, some having their surfaces roughened and cracked as if by fire, but others presenting no marks whatever, were met with. The former might have been used as heating-stones for boiling water in wooden vessels—the only ones found on the crannog—the latter as sling-stones or missiles.

Anvil.—About a foot below the surface, and a few feet to the north of the upper fireplace, a beautiful quartz pebble was found, which has the appearance of having been used as an anvil. It is of a circular shape, flat

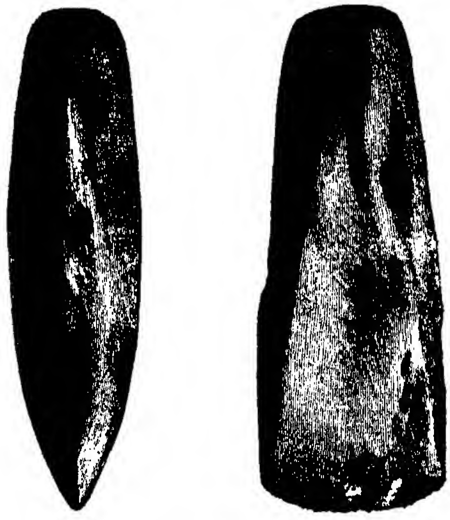

FIG. 2.—Stone Celt (Scale ½).

below, somewhat rounded above, and measures 27 inches in circumference.

Sharpening-Stones or Whetstones.—Five whetstones were collected from various parts of the island. They are made of a hard, smooth claystone, one only being made of a fine-grained sandstone, and vary in length from 5 to 7 inches.

Polished Celt.—Only one polished stone celt was found. It is a wedge-shaped instrument 5½ inches long and 2 broad along its cutting edge, which bears the evidence of having been well used, and tapers gently towards the other end, which is round and blunt. It is made of a hard mottled greenstone (Fig. 2.).

Querns.—Five upper, and portions of several lower quern stones were disinterred at different periods, all of which, however, with the exception of a pair found over the log pavement, and an upper stone observed towards the west margin of the crannog, were imbedded in the *débris* not far from the site of the fireplaces. Some are made of granite, while others are of schist or hard whinstone.

Cup-marked Stones.—Two portions of red sandstone, having cup-shaped cavities about 1 inch deep and 3 inches in diameter, were found amongst the *débris*. One of them was lying underneath, and as if supporting one of the horizontal raised beams at the north side of the

crannog. The other, the position of which was not determined, has two circular grooves or rings round the cup, the outer of which is 9 inches in diameter (Fig. 3).

FIG. 3.—Cup Stone (Scale $\frac{1}{3}$).

Other Stone Relics.—Amongst a variety of other stone relics there is one peculiar implement manufactured out of a bit of hard trap-rock. It presents two flat surfaces 3 inches in diameter, with a round periphery, and is $1\frac{3}{8}$ inch thick.

Flint implements.—Only three flint implements were found on the crannog—a large knife flake 3 inches long and $1\frac{1}{4}$ inch broad; the posterior portion of another flake; and a beautifully-chipped horseshoe-shaped scraper here figured (Fig. 4).

Spindle whorls.—Three small circular objects, supposed to be spindle whorls, are here classed together. Two are made of clay, and were found in the relic bed near the fireplaces. The smaller of the two (Fig. 5) is

FIG. 4.—Flint Scraper (Scale $\frac{1}{1}$).

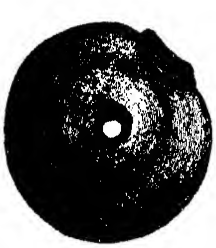

FIG. 5.—Clay Spindle Whorl (Scale $\frac{1}{1}$).

$1\frac{1}{4}$ inch in diameter, and has a small round hole in the centre; the other has a diameter of $1\frac{3}{4}$ inch, and is only partially perforated, just sufficiently to indicate that the act of perforation had been commenced, but not completed. The third object is a smooth, flat, circular bit of stone, $1\frac{1}{2}$ inch in diameter and $\frac{1}{2}$ inch thick, and is perforated in the centre like a large bead.

(*To be continued.*)

NOTES

THE Royal Society of Edinburgh has awarded the Keith Medal for the biennial period 1877-79 to Prof. Fleeming Jenkin for his paper on the application of graphic methods to the determination of the efficiency of machinery.

PROF. HENRY J. S. SMITH, F.R.S., Savilian Professor of Geometry in the University of Oxford, has been made a Corresponding Member of the Academy of Science of Berlin.

ON the 16th inst. the International Congress of Meteorology will meet at Vienna.

THE honorary degree of LL.D. has been conferred by the University of Glasgow on Mr. Edward John Routh, M.A., F.R.S., and Dr. Michael Foster, F.R.S.

PROF. W. H. FLOWER, LL.D., F.R.S., will give a discourse at the Royal Institution, on Fashion in Deformity, at the evening meeting on Friday, May 7.

PROF. HUXLEY will deliver the inaugural address at the opening of the Science College at Birmingham on October 1.

SIR WILLIAM THOMSON will preside at the meeting of the Physical Society on Saturday afternoon, and will make some brief communications to the Society.

PROF. HENRY TANNER, F.C.S., Senior Member of the Royal Agricultural College, and Examiner in the Principles of Agriculture under the Government Department of Science, has been appointed Professor of the Principles of Agriculture in the Royal Agricultural College, Cirencester.

THE fifty-first anniversary meeting of the Zoological Society was held last week. The report of the council was read by Mr. Sclater, F.R.S., the secretary. It stated that the number of Fellows on December 31, 1879, was 3,364 against 3,415 at the same date of the previous year, 145 new Fellows having been elected, and 189 removed by death or other causes during the year. In consequence of the bad weather, which had seriously affected the garden receipts, and of the general depression in business which had prevailed in 1879, the income of the society showed a falling off as compared with that of 1878, but not to any serious amount; the total receipts having been 26,463*l.* in place of 27,944 in 1878. The total assets of the society on December 31 last were estimated at 28,051*l.*, and the liabilities at 9,960*l.* The number of visitors to the gardens in 1879 had been 643,000, against 706,713 in 1878.

THE general meeting of the German Geometrical Society will be held at Cassel on July 4-7 next.

IN the last week of April an extraordinary fact was observed at Montsouris. We have stated already that the electrical observations are taken eight times daily with a Thomson electrometer and recorded; out of the eight readings registered on April 28 not less than six were negative, and on the following day seven were of the same sign. The occurrence is so extraordinary that it has been referred to in the papers as a fair characteristic of the season.

A LARGE and influential committee of shipbuilders and marine engineers has been formed in Glasgow for the purpose of promoting an exhibition of naval and marine engineering models in Glasgow. It is proposed that the exhibition shall be opened in the Corporation Galleries in November and remain open for six months. Mr. James Paton, the Superintendent of the Glasgow Museum and Galleries, has been appointed Secretary to the Committee.

AT the next meeting of the Society of Telegraph Engineers Dr. Siemens is going to bring forward his latest development of his dynamo machine, and of the influence of the electric light on vegetation.

THE Whit-Monday excursion of the Geologists' Association will be to Oxford, under the direction of Prof. Prestwich and and Mr. James Parker. It will last over two days. The long excursion of the Association will be to Bristol on August 2 and following days.

FROM the Report of the New York Central Park Menagerie we learn that that establishment has now 423 mammals, repre senting 56 genera and 98 species; 753 birds, of 102 genera, 134 species; 30 reptiles, of 8 genera and 10 species; or 1,206 animals in all. The additions in 1879 numbered 668.

HEYWOOD of Manchester has issued, for the small price of sixpence, the eleventh series of the Manchester Science Lectures for the People, containing lectures on "Islands," by Mr. A. R. Wallace; "The Age of Dragons," by Mr. B. W. Hawkins; "Palestine in its Physical Aspects," by Canon Tristram; and

"Traps to Catch Sunbeams," by Capt. Abney. We are sorry to learn from Prof. Roscoe's preface that the interest in these lectures having died out, they are to be discontinued. Nevertheless, as he says, they have undoubtedly done great good both when delivered and in the remarkably cheap form in which they have been published. The series, as a whole, has been a genuine success.

We understand that Dr. James Geikie, F.R.S., will shortly send to press a work entitled "Prehistoric Europe—a Geological Sketch," which treats of the principal climatic and geographical changes which have taken place in our continent since the commencement of the Pleistocene or Quaternary period. Mr. Stanford will be the publisher.

The Council of the Society of Arts have decided to summon a public Conference to consider the question of supplying London with pure water. The date for the Conference has been fixed for Monday, May 24, and succeeding days. The arrangements for the Conference are now being considered by a committee, and full announcements will be made as early as possible.

Since November last, instruction by means of lectures and laboratory practice, in connection with the City and Guilds of London Institute for the Advancement of Technical Education, has been given during the evening in Chemistry and Physics as applied to the Arts and Manufactures, by Prof. Armstrong, Ph.D., F.R.S., and Prof. Ayrton, A.M. Inst. C.E., in rooms at the Cowper Street Schools, Finsbury. On and after May 10, day classes will also be established, adapted to the scientific requirements of persons partially engaged, or intending to engage, in the manufacturing industries. The object of these day classes is to afford such preliminary training as is necessary for those who may desire, later on, to study particular branches of Applied Chemistry or Physics, for which special accommodation will be provided in the new buildings. Two courses, each of twenty-four lectures, in Chemistry and Physics will be given on two afternoons per week during May, June, and July, for imparting such knowledge of the general principles as is necessary for the after-understanding of the various branches of Applied Chemistry and Physics:—Chemistry, Wednesdays and Fridays, at 3 to 4 o'clock; Physics, Wednesdays and Fridays, at 4 to 5 o'clock. Prof. Ayrton will also give a special laboratory and tutorial course in Electrical Engineering; and Prof Armstrong will give a similar course for instruction in Photographic Chemistry. Students desirous of attending either of these courses are requested to communicate with the respective Professors at the present temporary laboratories, Cowper Street, Finsbury, E.C., before May 10, stating the times at which they could attend, and the maximum number of hours they could devote to the subject.

We learn from Catania, under date April 26, that the inhabitants were apprehending an eruption of Etna. An immense cloud of smoke has been observed.

A Parisian speculator has inaugurated the aëronautical season by a private ascent on April 25 at La Villette gasworks. The balloon, of only 300 cubic meters capacity, bore one aëronaut, with 30 kilograms of handbills, which were distributed all over Paris. The wind being slight, with a favourable direction, thousands of these prospectuses were picked up by street passengers and largely read. The whole expense of the aërial expedition, gas and everything, did not exceed 10*l.* sterling.

The phylloxera has made its appearance in the vineyards on Vesuvius and the opposite part of the Gulf at Puzzuoli and Pianura. Much alarm prevails. Precautionary measures are being taken. In Sicily the phylloxera, till now confined to Caltanisetta, is likewise reported near Messina.

At the Annual Meeting of the Royal Institution on May 1, the Annual Report of the Committee of Visitors for the year 1879, testifying to the continued prosperity and efficient management of the Institution, was read and adopted. The real and funded property now amounts to nearly 85,000*l.*, entirely derived from the contributions and donations of the Members. Forty-nine new Members paid their admission fees in 1879.

The *Japan Gazette* states that the line of railway which has been in contemplation for some time past between Tokio and Mayebashi will soon be commenced. The surveys are completed, and it is said that the line will traverse a rich district, and is expected to prove a great benefit to the country.

An exhibition of apparatus and products relating to bee-culture will be held at Schwerin on August 28-30 next.

The Electrotechnical Society at Berlin, which was founded on December 20, 1879, begins the second quarter of its existence with no less than 1,248 members.

The Emperor of Austria has presented the large gold medal "for arts and sciences" to Dr. Karl Ritter von Scherzer in recognition of his latest work, "Die britischen Welt-Industrien."

The *Report* of the Rugby School Natural History Society for 1879 is fairly encouraging. Several creditable papers are given by the members; we should like to see more papers of this class and fewer lectures by grown-up outsiders, some of which seem to us quite inappropriate in a *Report* of this kind.

"The International Dictionary for Naturalists and Sportsmen in English, French, and German," by Mr. Simpson-Baikie (Trübner and Co.), is a very useful book of reference, and contains a good many scientific terms, especially connected with natural history.

"The Sportsman's Guide" to the rivers, lochs, moors, and deer forests of Scotland comes once more to remind us of the hills and the heather, and to recall the memory of pleasant days spent on loch and river. It bears evidence of careful revision, and we are sure will prove useful to the tourist of scientific tastes, even if he be no disciple of the rod or gun.

It is known that M. Jamin, member of the French Institute, has patented an electric lamp in which the light is directed by an electrical current. A public company has been formed with a capital of 8,000,000 francs for the working of the patent.

The French Minister of Fine Arts has entered into an agreement with the Jablochkoff Electric Light Company to light the palace during the whole of the two months devoted to the exhibition. The number of lights fed by the machinery is about 400, and the motive power regarded at about 320 horses. The inauguration was to take place on May 1, and a large crowd had congregated to witness the process. But the crank of one of the principal engines broke, and it was necessary to postpone the opening for a few days. In spite of the growing opposition of the friends of the gas company, M. Garnier, the architect of the Paris Opera, will establish a trial of the principal electrical burners, to decide which is the more really fit for use in the house.

The additions to the Zoological Society's Gardens during the past week include a Common Ocelot (*Felis pardalis*) from South America, presented by Mr. Stephenson Clarke; two Elliot's Guinea Fowls (*Numida ellioti*) from East Africa, presented by the Rev. Thos. Wakefield; two American Barn Owls (*Strix flammea*) from Jamaica, presented by Mr. G. E. Dobson, C.M.Z.S.; a Koala (*Phascolarctus cinereus*) from South-East Australia, a Grey Squirrel (*Sciurus cinereus*) from North America, two Blue-streaked Lories (*Eos reticulata*) from Timor

Laut, two Prince Albert's Curassows (*Crax alberti*) from Columbia, purchased; two Common Foxes (*Canis vulpes*), four Chilian Pintails (*Dafila spinicauda*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

THE COMET OF 1106.—Amongst the comets which were thought to present certain indications of identity with the great comet of 1843 was that recorded by a large number of European historians, as well as in the Chinese Annals, in the year 1106. The circumstances of its appearance may be thus briefly stated: On the 4th of February, or, according to others, on the 5th, a star was seen which was distant from the sun "only a foot and a half"; it was observed from the third to the ninth hour of the day. Matthew Paris and Matthew of Westminster distinctly term it a comet. Pingré, not having the experience of the comet of 1843 as a precedent, questioned the possibility of seeing one of these bodies at so small a distance from the sun as the above expression may be taken to imply. Now, however, we are able to connect, with much probability, the star viewed in the day-time with the comet which on February 7 was discovered in Palestine about the commencement of the sign Pisces. On this day, we are told by three contemporary writers, a comet appeared in that quarter of the sky where the sun sets in winter, and occasioned great surprise; a white ray extended from it to a great distance. From the time of its first appearance "the comet itself and the ray, which had the whiteness of snow, diminished day by day." Others, on the contrary, say that the train, which had a more than milky whiteness, appeared to increase daily. In the west of Europe it does not seem to have been remarked till February 16 or 18. According to some writers it was visible only a fortnight, others say that it continued to shine for forty days, or during the whole of Lent, from February 7 to March 25; an eye-witness records that after fifty days the most acute vision only sufficed to distinguish it with difficulty. There is similar contradiction respecting the aspect of the comet, though most of the historians testify to its great brightness and apparent magnitude. On February 10, according to Gaubil's manuscript, used by Pingré for his "Cometographie," it was near the end of the sign Pisces, with a tail 60° in length. European chronicles mention that the tail extended to the beginning of the sign Gemini, under the constellation of Orion, whence, as Pingré points out, the latitude of the comet must have been south, while as the sun was in 25° of Aquarius, it could hardly be less advanced than 10° or 12° of Pisces to be seen in the evening after sunset. Thence, about February 16 or 18, it moved to the western quarter of the heavens, and after many days had elapsed, as Pingré records: "La comète parut du côté du septentrion vers l'occident: sa queue, semblable à une grand poutre, regardoit la partie du ciel qui est entre le septentrion et l'orient; on la voyoit jusque vers le milieu de la nuit. Durant vingt-cinq jours elle brilloit de la même manière à la même heure." Williams, in his account of comets mentioned in the Chinese annals, has a notice of the one in question. In the reign of Hwuy Tsung, the 5th year of the epoch Tsung Ning, the 1st moon, day Woo Seuh (1106, February 10), a comet appeared in the west. It was like a great Pei Kow (a kind of vessel or measure). It appeared like a broken-up star. It was 60 cubits in length and 3 cubits in breadth. Its direction was to the north-east: it passed the sidereal division Kwei (determined by β, δ, ϵ Andromedæ and stars in Pisces), and through the divisions Lew (determined by α, β, γ Arietis), Wei (by the three stars of Musca), Maou (by the Pleiades), and Peih (by α, γ, δ, &c., Tauri). It then entered the clouds and was no more seen. Williams, doubtless influenced by this last expression, and the object having been said to resemble a broken-up star, and probably overlooking the presence of the comet recorded by the European historians in the same part of the sky, adds: "This appears to have been a large meteor, as it seems to have been seen for a short time only." But there can be little hesitation, we think, in identifying the body remarked in China with the European comet, its track through the constellations, as given by Williams, which agrees with Gaubil's manuscript, representing very satisfactorily the particulars found in the European chronicles.

In 1843 Laugier and Mauvais, reducing their elements of the great comet of that year to 1106, and assuming the perihelion passage to have taken place on February 3, found the following geocentric track.

Feb. 4,	Long. 324°,	Lat.	−3°	Feb. 16,	Long. 4°,	Lat.	−23°
7,	„ 335,	„	−10	March 5,	„ 40,	„	−28
10,	„ 345,	„	−16	25,	„ 60,	„	−27

And they conclude, "en admettant que la comète de 1106 est une apparition de la comète de 1843, toutes les observations sont satisfaites." It is not easy to see how such an inference can have been drawn in face of the circumstances mentioned by the historians during the later period of the comet's visibility, when it was seen to the north of west, with a tail extending towards *the north-east*; a condition wholly incompatible with the elements of the comet of 1843, which body did not remain on the northern side of the ecliptic so long as three hours. On reducing Hubbard's parabola of 1843 to 1106 we have the following positions, assuming perihelion passage February 3·5 G.M.T.:—

G.M.T.	h.	Long. °	Lat. °	Log. *r*.	Log. Δ.	Intensity of Light.
Feb. 4,	0 ...	322·9 ...	− 1·7 ...	8·8080 ...	9·9704 ...	277·6
19,	8 ...	12·6 ...	−25·1 ...	9·8377 ...	9·9543 ...	2·6
March 25,	12 ...	60·3 ...	−27·3 ...	0·1725 ...	0·2619 ...	0·13

These places are in agreement with those found by Laugier and Mauvais; that for March 25 corresponds to R.A. 63°·7, Decl. −6°·4.

It is well known that the comet of 1106, with better reason, was long supposed to be identical with the famous comet of 1680. That point has been discussed elsewhere. Our object now, since the possibility of the identity of the comet of 1106 with that of 1880 and 1843 has been again mooted, is to draw attention to the main difficulty that exists in the acceptance of the idea.

PHYSICAL NOTES

M. ANTOINE BREGUET, at a lecture upon Recent Advances in Telegraphy, exhibited some ingenious apparatus illustrating the principles of the duplex and quadruplex telegraph, the actions of the electric currents being most successfully represented by the flow of water in tubes.

PROF. CARMICHAEL describes, in the *American Journal of Science*, a device for rendering the sonorous vibrations of a flame visible to a whole audience. He passes coal-gas through a König's manometric capsule, and then leads it by a tube into a burner inclosed in a small mica cylinder or lantern, which is rotated either in a vertical or a horizontal plane. The ring of light thus produced is broken up by the sonorous vibrations into a serrated form, the forms of the serrations varying with the nature of the sound. To increase the brilliance of the light the gas is previously passed over a sponge soaked in some volatile hydrocarbon such as "gasoline" or "benzoline," and oxygen is also supplied into the mica lantern. A shrill whistle produces very fine serrations invisible thirty feet away. The human voice at ordinary loudness produces serrations two or three inches deep round the ring. A modified capsule placed upon the various parts of a vibrating body serves to investigate their modes of vibration, nodal points, &c.

SOME curious experiments on the magnetic behaviour of elder-pith have lately been made by M. Ader. Pith-balls placed in a powerful magnetic field are strongly attracted.

PROF. ROWLAND contributes a long and careful memoir upon thermometry and the mechanical equivalent of heat to the *Transactions* of the American Academy of Arts and Sciences. His results differ by about ·25 per cent. from the accepted numerical determinations of Joule's equivalent. Amongst other matters noticed in this memoir is an alleged decrease in the specific heat of water at higher temperatures.

A CONTEMPORARY gives the following method of illustrating the indestructibility of matter:—Two sealed glass tubes of equal weight, one of them containing oxygen and a little powdered charcoal, are prepared. The charcoal may be caused to burn away completely by heating it by means of a small flame. On placing the two tubes on a balance it will be seen that there has been no variation in weight.

THE process of electrodeposition is now finding a useful application in the production of bronze statuary, where it promises to supersede the process of casting. The Electrometallurgical Company of Brussels have just produced a colossal statue of Van

Eyck by the deposition of copper electrically upon the clay model. The production of bronzes may be readily carried out on a small scale by the following process communicated to the *Natural History Journal*, and which possesses some elements of novelty. Take any plaster figure or group, boil in sterine, then blacklead and plunge in a copper bath. Attach a very weak battery, and deposit very slowly a *thin* coating of copper. Now remove from the bath, and bake in an oven until the plaster model shakes out in dust. You have now a very thin copper reproduction of your model. Varnish this outside so as to prevent the further deposition, and replace in the bath. The copper will now be deposited on the inside surface, and you can thicken up to any desired point. For this second process a much stronger battery may be used.

MM. Leclerc and Vincent have described to the Physical Society of Paris an electrical instrument which will automatically record the notes played upon a piano. It can be adapted to a piano of any construction.

Clöe's thermoelectric pile has been recently improved by an addition which obviates the injurious effect of sudden and excessive heating of the junctions arising from alteration in the pressure of the gas. This safety-apparatus consists of a small glass vessel about half filled with water, and closed by a cork stopper, through which pass two tubes, one going to the bottom and being a branch of the tube by which the gas comes to the pile, while the other is shorter, and conducts any gas that may pass through it from the vessel to a gas-burner on another branch constantly lit. If the pressure of the gas is weak the water closes the mouth of the longer tube; if it increases the gas issues in bubbles in the liquid and rises through the shorter tube to the gas jet, where it is lit. The arrangement is a sort of safety-valve, and prevents the pressure from exceeding a certain amount, which is regulated at will.

M. Marcel Deprez has devised an ingenious apparatus for transmitting a movement of rotation by electricity. The apparatus is composed of a transmitter and a receiver. The transmitter consists of two ordinary split-collar commutators set upon a common axis, but adjusted at right angles to each other. The receiver consists of two longitudinal armatures carrying coils of wire as employed in the earlier Siemens' magneto-electric machines. These also run on a common axis and in positions at right angles to one another: and they are placed in the magnetic field between the poles of a permanent magnet. Currents generated by a battery pass through the transmitter and are conveyed by wires to the receiver. For every position of the axis of the transmitter there is one position—and one only—of stable equilibrium for the axis of the receiver. Hence the axis of the receiver follows all the movements of the transmitter; turns at the same rate and in the same direction as the transmitter may be turned; and makes the same number of revolutions precisely to within a quarter of a revolution.

GEOGRAPHICAL NOTES

The new number of the Geographical Society's *Proceedings* is chiefly occupied with a narrative of Lieut. G. T. Temple's voyage on the coasts of Norway and Lapland, illustrated by a map on which the depths of the ocean are well shown in colour, and by Mr. E. Hutchinson's account of Mr. Ashcroft's ascent of the River Binué last August, with remarks on the systems of the Rivers Shary and Binué. With the latter paper is given a reduction of Mr. Flegel's map of the Upper Biuné from his own surveys, recently issued by Hellfarth of Gotha. An interesting letter from Mr. Thomson is afterwards given, furnishing information as to the progress of the East African Expedition. Among the geographical notes may be mentioned a summary of the most recent rumours respecting Prejevalsky and a description of routes from Dzungaria into Tibet. There is also an account of a visit paid by Mr. Woolley, of the Consular service, to the Island of Tsushima and Corea, and of the Rev. J. Chalmers's recent explorations in the interior of New Guinea, in the course of which he traversed a considerable extent of previously unknown country. The notes are followed by a communication on the "Tal-Chotiali Route from India to Pishin and Candahar," furnished by Mr. G. W. Vyse, who was attached to the Tal-Chotiali Field Force, in correction of previous statements made respecting this route.

By a note received on April 28 we learn that the Howgate Arctic Expedition Bill passed the House of Representatives at Washington on the 15th inst., and has gone to the Senate for final action. "This is a great step in advance, and augurs well for Government aid to the Expedition."

Under the title of "La Exploradora" an association has been formed in Spain, through the instrumentality of Señor Don Manuel Iradier, for the exploration and civilisation of Central Africa, and in furtherance of its objects commenced the publication of a *Boletin* in March. This association proposes to despatch an expedition from the west coast with what appears to be a somewhat ambitious programme. Its starting-point would be the Bay of Corisco, whence it would traverse the Sierra de Cristal, and afterwards march by way of Mount Onschiko and the River Eyo towards Lake Albert. If successful so far, it would then visit Mount Gambaragara, in the Usongora range, to study the peculiar population said to be found there. Then, turning in a north-westerly direction, it would make its way back to the Gulf of Guinea by Lake Liba and the Cameroons River. It is proposed that this expedition should start at latest during the month of June, but we are not aware whether the necessary funds for its journey of fourteen months have been provided. In the course of their march it is intended that the members of this expedition should devote themselves to the study of all the important problems yet unsolved in the central region of the African continent, and especially whether there be any connection between Lake Liba and the rivers Shary and Binué.

It is stated that the Comte de Semellé is about to return to Africa, in order to undertake an exploring expedition up the river Binué.

Dr. Regel, director of the Imperial Botanical Garden of St Petersburg, gave an account of the Flora of Turkestan at a recent meeting of the St. Petersburg Horticultural Society. Turkestan may be divided into two distinct parts—the west, with a very mild climate, and the east, the climate of which is almost that of St. Petersburg. The flora of Turkestan is exceedingly varied, much resembling that of Central Asia; plants proper to the climate of Europe grow there in small numbers. The eastern part abounds in Alpine specimens, and in general its vegetation approaches that of Europe, although quite as often plants are met with which are the sole product of Central Asia. Turkestan possesses neither lily nor tulip, and has very few conifers.

Last week we referred to Mr. E. Whymper's mountaineering exploits in South America. Some further details are given by Mr. Whymper himself in a letter to Mr. F. F. Tuckett in Tuesday's *Times*. It is dated from Quito, March 18. He says:—"You will be glad to hear that I have succeeded in polishing off Chimborazo, Corazon, Sincholagna, and Antisana. We have also passed twenty-six consecutive hours on the top of Cotopaxi. This last I reckon a feat, and I am not aware that any one has ever before encamped at so great an altitude as 19,500 feet. Antisana is the most difficult of those we have been up, and few more difficult ascents have ever been made. We are now going off to Cayambe, the mountain on the Equator, and shall try on the same journey to polish off Saranen and Cotocachi. Cayambe is thought to be an active volcano, but it is not certain that this is the case, neither is its height well determined. The height of Saranen is not known, but it *is* high. Cotocachi is the volcano which destroyed Ibarra some years ago, and is reputed to be 16,300 feet high. We have grown out of being affected by rarefaction of the air, and can be quite gay and lively at 19,000 feet. At first I was fairly knocked over by it, and was rendered quite incapable. The Carrels also were nearly as bad. The climate of Ecuador is the most utterly abominable that can be imagined. We have not had one single day fine from beginning to end, and not one view from a mountain top. An hour of clear weather from 6 to 7 a.m. is the most you can reckon on, and after that everything is bottled up in a mist. We carry about mercurial barometers everywhere, and boil water to an extent that would delight your heart."

In the May number of their *Chronicle* the London Missionary Society announce the departure, on April 16, of a new expedition for East Central Africa, to reinforce the weakened and scattered party now there. The Rev. A. J. Wookey goes to join Mr. Hore at Ujiji, the Rev. D. Williams to Urambo, where Dr. Southon now is, and Mr. W. S. Palmer, a medical missionary, to Uguha, where, we presume, he will be stationed at Mtowa, near the Lukuga Creek.

In their just-issued eighty-eighth Report the Committee of the Baptist Missionary Society summarise the efforts of their

Congo Expedition to reach Stanley Pool by way of San Salvador and Makuta. Owing to tribal jealousies, the Makuta route has had to be given up, but fresh efforts are now being made to discover some other route to the Upper Congo by Zombo or Sanda; or should these prove unfavourable, to strike out an altogether new road, and so to reach Stanley Pool over hitherto untrodden ground. By latest advices it seems probable that they may be able to get there by Sanda (about two days' journey from Makuta), where Messrs. Comber and Crudgington have been well received, and have been allowed to establish a station.

A "Thüringer Wald" Club, similar to the various Alpine clubs, has recently been formed at Eisenach. An "Erzgebirge" Club is in course of formation at Joachimsthal (Bohemia). A Saxon Club for the closer investigation of the last-named mountain chain has existed for several years; also a "Rhöngebirge" Club. These clubs do great service to tourists and the general public, and would be well worth imitating in our own mountain districts.

Mr. Stanford has issued three nicely-printed maps in which the results of the recent elections are very clearly shown for England, Scotland, and Ireland. The maps have been designed by Miss E. Shaw-Lefevre.

Mr. Stanford has just published a "Geography for Little Children," by Mrs. Zimmern, which in a very simple and interesting way attempts to show the use of a map and teach some of the elementary points of physical geography. Its numerous attractive and quite original illustrations are an important feature. We have also received the forty-fifth edition of Cornwell's "Geography for Beginners."

SCIENTIFIC SERIALS

The *Journal of Anatomy and Physiology, Normal and Pathological*, vol. xiv. Part 3, April.—Prof. Turner, the structure of the comb-like branchial appendages, and of the teeth of the basking shark (*Selache maxima*) (with a plate).—Dr. G. Thin, on the ganglion-cells of the elephant's retina.—Dr. J. H. Scott, on the structure of the style in the tongue of the dog.—Dr. A. H. Young, on the anatomy of the Indian elephant.—Dr. C. Creighton, illustrations of the pathology of sarcoma, from cases of subcutaneous cystic tumours (three plates).—Dr. Dreschfeld, on a peculiar form of liver tumour (with a plate).—On a case of cerebellar tumour (with a plate).—Dr. T. Oliver, post-mortem in a case of extreme obesity.—Prof. J. Young, on the head of the lobster (with a plate).—W. S. Richmond, new abnormalities of the arteries of the upper extremity, with a plate.—Dr. R. J. Anderson, abnormal arrangement of the thyroid arteries (with a plate).—On a variety of the mylo-pharyngeus and other unusual muscular abnormalities.—Drs. P. M'Bride and A. Bruce, the pathology of a case of fatal ear-disease (with a plate).—Dr. F. Shepherd, notes on the dissection of a case of congenital dislocation of the head of the femur.—J. D. Brown, abnormal cystic artery.—Anatomical notes.

Journal of the Royal Microscopical Society, vol. iii. No. 2, April, 1880.—A. D. Michael, a further contribution to the knowledge of British Oribatidæ, Part 2, with the assistance of C. F. George (two plates).—Dr. Lionel S. Beale, annual address as president.—J. W. Groves, on a means of obviating the reflection from the inside of the body tubes of microscopes, with suggestions for standard gauges for the same and for sub-stage fittings.—A. Nachet, on a petrographical microscope.—The record of current researches relating to invertebrata, cryptogamia, microscopy, and bibliography.—Proceedings of the Society.

Revue Internationale des Sciences, April.—M. Gilkinet, on the development of the vegetable kingdom in geological times.—A. de Bary, on apogamous fungi, and on apogamy in general.—R. Blanchard, on striated muscles in the monomyary acephalous mollusks, and on the peritoneum of Seba's python.

The *American Naturalist*, vol. xiv., No. 3, March.—G. Macloskie, the proboscis of the house-fly.—E. Coues, sketch of progress in mammalogy in the United States in 1879.—E. D. Cope, a review of the modern doctrine of evolution, being an abstract of a lecture delivered before the Californian Academy of Sciences (with several cuts of crania of Anura).—E. A. Smith, a paper concerning amber.—Notes on recent literature, General Notes, and Scientific News.

No. 4, April.—W. S. Barnard, protoplasmic dynamics (an attempt to find a clue "to the mode in which molecular movement is transformed into the movement of masses").—C. S. Minot, a sketch of comparative embryology (II., the fertilisation of the ovum).—C. A. White, on the progress of invertebrate palæontology in the United States for the year 1879.—E. D. Cope, a review of the modern doctrine of evolution (concluded).—A. J. Cook, on the tongue of the honey-bee.—Notes on recent literature, General Notes, Proceedings of Scientific Societies.

Verhandlungen der k. k. zoologisch-botanischen Gesellschaft in Wien, vol. xxix. Part ii., June to December, 1879, Vienna, 1880, contains, besides list of members and minutes of the Proceedings, the following memoirs:—Otto Bohatsch, supplement to the lepidopterous fauna of Syria.—H. Wichmann, the minute anatomy of the seeds of *Aleurites triloba*, Forst. (two plates).—Dr. J. Csokor, on the pimple mite, and on a new variety of the same occurring in swine (*Demodex phylloides*), one plate.—H. Leder, contribution to the coleopterous fauna of the Caucasus.—S. Schulzer, mycological notes, iv.—E. Reitter, the synonomy of coleoptera; contributions to a knowledge of the European Pselaphidæ and Scydmænidæ: on new coleoptera from South-West Russia; on Spelæodytes, Mill.—Dr. H. Loew, analytical table to determine the North American species of Pachyrrhina, a genus of Tipulidæ.—C. R. Osten-Sacken, the Tanyderina, a remarkable group of the Tipulidæ.—F. von Thümen, two new leaf-frequenting ascomycetes, from Vienna.—A. von Pelzeln, on a fifth package of birds from Ecuador; on Dr. Breitenstein's collection of beasts and birds from Borneo.—Dr. F. Löw, notes on Psyllodidæ (with a plate); descriptions of new gall-insects, with notes on some species already known.—Dr. R. Bergh, contributions to a monograph of the Polyceridæ (with six plates).—W. Voss, materials towards a knowledge of the fungi of Carniola.—Dr. G. Mayr, on the ichneumon-wasp of the genus Telenomus.

The *Zeitschrift für wissenschaftliche Zoologie*, xxxiv. Band, Heft 1, March.—Dr. Ernst Nauck, on the masticatory apparatus of the Brachyura, with a plate and woodcuts.—Dr. Hubert Ludwig, on *Asthenosoma varium*, Grube; and on a new organ in the Cidaridæ, with two plates and woodcut. Describes three specimens from the Museum Godeffroy, one possibly a variety of *A. varium*, or possibly a new species, and describes five sac-like organs which lie, like the radial Y-shaped manubria (Gabelstücke), in the plane of the ambulacra. These he calls the cœcal sacs (Blindsacke) of the masticatory apparatus. Each cœcal sac consists of a thin membrane, stiff with calcareous spicules; right and left of each of these there lie two other blind appendages, but very much smaller; they were first detected in *Cidaris tribuloides*, but were also found in *C. metularia*, *Dorocidaris papillata*, and *Goniocidaris canaliculata*. A slight trace of their existence was found in *Diadema setosum*, but they were quite absent in the families Echinometridæ and Arbaciadæ.—Prof. Dr. P. Langerhans, on the worm fauna of Madeira; part 3, with three plates (to the end of the Nemerteans).—The same, on the Madeiran Appendicularia.—Dr. H. von Ihering, on *Graffilla muricicola*, a new parasitic Rhabdocœlian, with a plate (found in the kidney of *Murex trunculus* and *M. brandaris*, both at Naples and Trieste).

The *Revue des Sciences Naturelles*, 2e série, tome 1, No. 4, March 15.—Dr. A. Godron, on the axillary buds and branches in the Gramineæ.—L. Tillier, essay on the geographical distribution of marine fishes (conclusion).—S. Jourdain, on the morphology of the early stage of the generative organs of *Helix aspersa*, with a plate.—M. Leymerie, sketch of the Pyrenees of the department of Aude (in continuation), with a plate.—A Sabatier, the law of the correlation of forms and intermediate types.—E. Dubrueil, catalogue of the land and fluviatile mollusca of the department of Herault (conclusion).—Review of recent French works on zoology by Messrs. Jourdain, Rouzaud, and Dubrueil, and on botany and geology by M. Dubrueil.

Rivista Scientifico-Industriale, March 15.—Note on electricity and earthquakes, by Prof. De Bosis.—Researches on the diathermanous power of films of soapy water, by Prof. Marangone.

Archives des Sciences Physiques et Naturelles, March 15.—Swiss geological review for 1879 (continued), by M. Favre.—Enigmatic descriptions of natural groups, by M. de Candolle.—New observations on philippium, by M. Delafontaine.—On decipium and its principal compounds, by the same.—Earthquakes and their scientific study, by M. Heim.—On the density of chlorine at high temperatures, by M. Crafts.

SOCIETIES AND ACADEMIES

London

Royal Society, April 22.—"Effects of Electric Currents on the Surfaces of Mutual Contact of Aqueous Solutions." By G. Gore, LL.D., F.R.S.

In the year 1859 I made the following experiments, for the purpose of ascertaining whether visible movements, similar to those obtained by passing an electric current through mercury and an aqueous solution, could be obtained by passing a current through the surface of mutual contact of two aqueous liquids alone:—"1. A definite layer of oil of vitriol was placed beneath a layer of distilled water weakly acidulated with sulphuric acid, and the terminal wires of a voltaic battery immersed in the upper liquid; no visible movements occurred at the boundary line of the two liquids.

"2. A dense solution of cyanide of potassium was placed in a small glass beaker, a few particles of charcoal sifted upon its surface, and a layer of aqueous ammonia, half an inch deep, carefully poured upon it. A vertical diaphragm of thin sheet gutta-percha was then fixed so as completely to divide the upper liquid into two equal parts; the vessel was placed in a strong light, and two horizontal platinum wire electrodes, from sixty-six freshly-charged Smee's cells, were immersed one-eighth of an inch deep in the liquid ammonia on each side of the diaphragm. A copious current of electricity circulated, but no movement of the liquids at their mutual boundary line could be detected" (see *Proc. Roy. Soc.*, vol. x., 1860, p. 235, par. 9).

Recently, also, I have made similar experiments, but in a much more searching manner, in order to ascertain whether an electric current, passing between two aqueous liquids, affects their diffusion into each other. The essential difference in the form of these experiments from that of the above-mentioned ones was to concentrate the action of the current upon a very much smaller surface of contact of the liquids, and thus render any visible effect upon their diffusion more manifest.

After making several forms of apparatus, in order to obviate certain difficulties of manipulation which arose and were fatal to success, I found that, when an electric current was passed between the surfaces of mutual contact of certain aqueous solutions of different specific gravities, the boundary line of contact of the two liquids became indefinite at the surface where the current passed from the lighter into the heavier solution, and became sharply defined where the current left the heavier liquid and re-entered the lighter one; and that on reversing the direction of the current several times in succession after suitable intervals of time, these effects were reversed with each such change. Also, in various cases in which the contiguous boundary layers of the two liquids had become mixed, the line of separation of the two solutions became, by the influence of the electric current, as perfect as that between strata of oil and water lying upon each other. In rarer cases two such distinct lines of stratification appeared. Other new phenomena were also observed.

As I have sought, without success, for any record of previous discovery of essentially similar effects, and as it is evident that those I have observed belong to a large class of similar phenomena, I beg leave to take the earliest opportunity of submitting this brief statement to the Royal Society.

"Revision of the Atomic Weight and Valence of Aluminium," by J. W. Mallet, F.R.S.

The general mean from all the experiments, if all be included, is Al = 27·032, with a probable error for this mean of ± ·0045. If Series I, B, be excluded, the mean of all the remaining twenty-five experiments is Al = 27·019, with a probable error of ± ·0030.

The general result adds, the author hopes, aluminium to the, unfortunately still limited, list of those elementary substances whose atomic weights have been determined within the limits of precision attainable with our present means of experiment.

This result also adds one to the cases already on record of the numbers representing carefully determined atomic weights approaching closely to integers, and leads the author to say a word on the reconsideration of "Prout's Law." Taking the following eighteen elements as the only ones of which the atomic weights may be fairly considered as determined, with reference to hydrogen, with the greatest attainable precision, or a near approach thereto, namely, oxygen, nitrogen, chlorine, bromine, iodine, sulphur, potassium, sodium, lithium, silver, thallium, aluminium, carbon, phosphorus, barium, calcium, magnesium, and lead, and making a reasonable allowance for the errors of the determinations, he calculates the probability that nine of those numbers should lie, as they are found to do, within 0·1 of integers, supposing the value of the true numbers to be determined by chance, and finds it only as 1 to 235·2. The exact figure for the chance will of course depend upon the limit of error taken; but the above example seems sufficient to show that not only is Prout's law not as yet absolutely overturned, but that a heavy and apparently increasing weight of probability in its favour, or in favour of some modification of it, exists, and demands consideration.

Chemical Society, April 15.—Prof. H. E. Roscoe, president, in the chair.—The following papers were read,—On the lecture illustration of chemical curves, by E. J. Mills. The author has contrived an apparatus for exhibiting the variations in the actions of sulphuric acid on zinc and sodic hydrate on aluminium, produced by alterations (1) in the strength of the solution, (2) in the time during which the action is allowed to proceed. The gas evolved is collected in a series of inverted glass cylinders filled with water, arranged at equal distances. The surfaces of the water levels after the gas has been collected form a curve.—On the analysis of organic bodies containing nitrogen, by W. H. Perkin (continued). The author finds that a mixture of precipitated manganic oxide and potassium chromate (containing 10 per cent. of bichromate) in about equal parts kept at a temperature of 200°–250° C. is preferable to the chromate alone for absorbing the oxides of nitrogen.—On the volatilisation of solids in vacuo, by W. D. Herman. The author has obtained adamantine colourless transparent crystals of phosphorus by volatilising ordinary phosphorus in vacuous glass tubes in the dark. The crystals may be as long as 8 mm.; they turn red in sunlight. Similar experiments have also been made with sulphur, selenium, &c.—On the determination of nitric acid as nitric oxide by means of its reaction with ferrous chloride, by R. Warington. The author describes an apparatus for the above purpose. The air is expelled by carbon dioxide, the nitrate heated by a calcium chloride bath to 135° C., and the nitric oxide measured as gas; organic matter does not affect the results.—On the six possible isomeric dibromtoluols and other of the bromo- and bromonitro derivatives of toluol related thereto, by R. Nevile and A. Winther. The authors criticise the results of Wroblcosky, *Jahr.*, 1870, 528, and 1871, 450, and establish the conclusion that in such bodies the bromine never occupies a position which is "meta" to the amido group.

Zoological Society, April 20.—Prof. W. H. Flower, F.R.S., president, in the chair.—Prof. Owen, C.B., read descriptions of some new and rare Cephalopoda, to which were added notes on the occurrence of gigantic species of this group.—A second paper was read by Prof. Owen on the external and structural characters of the male of *Spirula australis*.—Dr. M. Watson read a paper on some points in the anatomy of the Proboscidea, in which he described the structure of the female organs of the Indian elephant, as observed in a specimen recently dissected.—Lieut.-Col. H. H. Godwin-Austen read a paper on the land-molluscan genus *Girasia* of Gray, and made remarks on its anatomy and on the form of the "*capreolus*" of Lister or the spermatophore, as developed in species of this genus of Indian *Helicidæ*.—A communication was read from Dr. Max Schmidt on the duration of life of the animals in the Zoological Garden of Frankfort-on-the-Main.—A communication was read from the Rev. O. P. Cambridge, C.M.Z.S., containing descriptions of new or little-known spiders of the genus *Argyrodes*.—A communication was read from Mr. Edgar A. Smith containing an account of a collection of the shells of Lake Tanganyika, and of the neighbourhood of Ujiji, Central Africa, made by Mr. E. C. Hore, of the London Missionary Society. Twenty-one species were represented in this collection, amongst which were two new generic forms proposed to be called *Tiphobia horei* and *Neothauma tanganyicensis*.

Geological Society, April 14.—Robert Etheridge, F.R.S., president, in the chair. Colville Brown, John N. Dufty, and George Benjamin Nichols were elected Fellows of the Society.—The following communication was read:—On a new Theriodont Reptile (*Cliorhizodon orenburgensis*, Twelvetr.) from the Upper Permian Sandstone of Kargalinsk, near Orenburg, in South-Eastern Russia, by W. H. Twelvetrees, F.L.S. The above measures are cupriferous, and rest on limestone with Zechstein fossils. Associated with the remains of Saurians and Labyrinthodonts are *Calamites*, *Lepidodendron*, *Aroides crassispatha*, Conifers, and a *Unio*. The specimen noticed in this

paper is apparently the dentary part of the left mandibular ramus, with the crowns of a canine, an incisor, and ten of the molars. The author describes the characteristics of these and the mode of implantation in the jaw, which accords with that described by Prof Owen in *Titanosuchus ferox*. The characters of this specimen resemble those of the genus *Rhopalodon;* but as there are some marked differences, the author proposes to name it *Cliorhizodon orenburgensis*.—The classification of the Tertiary period by means of the mammalia, by Prof. W. Boyd Dawkins, F.R.S., Professor of Geology in Owens College. The author, after some introductory remarks on the value of vertebrata and invertebrata in classification, pointed out that the mammalia become of especial value in the Tertiary period as undergoing more rapid change than the other classes, from their being, as it is happily termed, *en pleine évolution*. He discussed the characteristics of each of the great periods, as defined and limited by their mammalia, pointing out that throughout the Eocene these frequently exhibit relations more or less marsupial. Indeed it is not till the close of the Lower Miocene that the traces of this relationship are lost. In the Middle Miocene, *Sus, Cervus, Antilope, Felis, Lutra*, and *Castor* appear for the first time, and the higher apes were present in European forests. In the Upper Miocene, *Camelopardalis, Gazella, Hyæna*, and *Hystrix* appear. During the Pliocene several important genera disappear from the world or from Europe—among the latter the apes, at the close of the Upper Pliocene. Oxen, horses, bears, and elephants appear. Great changes took place in the Pleistocene; seven species survived into it which are now extinct, and of new-comers there were fourteen living and seven extinct species. *Cervus megaceros* is the sole survivor from the Pleistocene to the prehistoric period which has since become extinct. The paper concluded with some remarks on the latter part of the first and the second period, which, however, as forming the subject of previous notices, was treated more briefly. The author remarked that a study of the development of the mammalia renders it hopeless to expect to find man in the Eocene or Miocene, and improbable in the Pliocene.

Anthropological Institute, April 13.—Major-General A. Lane Fox, F.R.S., vice-president, in the chair.—The director read a paper on Fijian Burial Customs, by the Rev. Lorimer Fison. There is no uniformity of custom in Fiji, so that no description of what is done by any one tribe can be taken as applicable to all the others. The strangling of widows, however, that they might be buried with their dead husbands, seems to have been everywhere practised. The widow's brother performs the operation, and is thenceforward treated with marked respect by his brother-in-law's kinsfolk, who present him with a piece of land over which the strangling-cord is hung up. Should he, however, fail to strangle his sister, he is despised and ashamed to show his face. When a woman is about to be strangled she is made to kneel down, and the cord (a strip of native cloth) is put round her neck. She is then told to expel her breath as long as possible, and when she can endure no longer to stretch out her hand as a signal, whereupon the cord is tightened, and soon all is over. It is believed that, if this direction be followed insensibility ensues immediately on the tightening of the cord; whereas if inhalation has taken place, there is an interval of suffering. An excuse for the practice of widow-strangling may be found in the fact that according to Fijian belief, it is a needful precautionary measure, for at a certain place on the road to Mbulu (Hades) there lies in wait a terrible god, called Nangga-nangga, who is utterly implacable towards the ghosts of the unmarried. He is especially ruthless towards bachelors, among whom he persists in classing all male ghosts who come to him unaccompanied by their wives. Turning a deaf ear to their protestations, he seizes them, lifts them above his head, and breaks them in two by dashing them down on a projecting rock. Women are let off more easily. If the wife die before her husband, the widower cuts off his beard and puts it under her left armpit. This serves as her certificate of marriage; and, on her producing it to Nangga-nangga, he allows her to pass. On the island of Vanua Levu a noted "brave" is distinguished from the common herd after death by being buried with his right arm sticking out above the grave-mound, and passers-by exclaim with admiration as they look upon the fleshless arm, "O the hand that was the slayer of men!" For some days after the decease of a ruling chief, if his death be known to the people, the wildest anarchy prevails. The idea seems to be that not until decomposition may be supposed to have made considerable progress is the dead man fairly done with, and his authority handed over to his successor. Hence the death of a ruling chief is studiously concealed for a period varying from four to ten days. By many tribes the burial-place of their chief is kept a profound secret, lest those whom he injured during his lifetime should revenge themselves by digging up and insulting, or even eating, his body. Hence the surface sods are raised with extreme care, in order that they may be replaced with as little derangement as possible. Cave burial is common in Fiji, although by no means universal; in some cases artificial caves are made, either in the side of a hill, or by sinking a perpendicular shaft, and then putting in a "side drive," as the Australian gold-diggers call it; this forms the grave, and here the chief lies with his strangled women under him. A stone closes the entrance of the chamber and excludes the earth when the shaft is filled up. On the death of the king of the Nakelo tribe three old men come, with fans in their hands, and conduct the spirit to the banks of the river. Here they call upon Themba—the Nakelo Charon—to bring over his canoe, and wait until they see a wave rolling in towards the shore, which they say is caused by the approach of the invisible canoe; they then avert their faces, point their fans suddenly to the river, cry aloud, "Go on board, sir," and forthwith run for their lives, for no eye of living man may look upon the embarkation. The grave is dug about hip deep, the body laid in it, and an old cocoanut is broken by a blow with a stone, being so held that the milk runs down upon the head of the corpse. The meat of the nut is then eaten by the three elders, and the grave is filled up.—A paper on the Polynesian Race, by C. Staniland Wake, M.A.I., was read. The author proposed to show, first, that the Polynesian Islanders must be described as a bearded rather than a non-bearded race, and secondly, that, as a rule, they are well acquainted with the use of the bow and arrow, and quoted the observations of numerous travellers in support of his view.—Major-General A. Lane Fox, F.R.S., exhibited some paintings and bead mats, the work of Bushmen.

Physical Society, April 24.—Prof. W. G. Adams in the chair.—New members:—The Marquis of Blandford, Mr. J. Marshall.—Prof. G. C. Foster read a note by Prof. Rowland, of Baltimore, U.S., on the discovery of Mr. Hall that a magnet exercises an electromotive on a current in a conductor crossing its field, as well as a force on the conductor itself. This fact will render it necessary to apply a correction to equations which assume that only the latter force acts. The electromotive force in question is at right angles to the direction of the current and to the lines of magnetic force. Prof. Rowland expresses it mathematically in this note, and bases a new method of determining the value of v, the ratio of the electrostatic to the electromagnetic unit of electricity, which gives v almost identical with the velocity of light, thus confirming Clerk-Maxwell's theory of the nature of light. Dr. J. Hopkinson, F.R.S., suggested an expression for one of Prof. Rowland's results.—Prof. Foster also read a note by Prof. Wild, of the Central Russian Meteorological Observatory, on a mode of correcting the bifilar magnetometer for torsion of its fibres, &c., and a method for finding the horizontal component of the earth's magnetism by its aid.—Mr. Ridout, F.C.S., described an improved thermo electric apparatus of his construction. The author has followed the idea of combining the thermopile and galvanometer in one instrument on the same base-board. The defects of the apparatus as ordinarily made are a too great disparity between the resistance in the pile and in the galvanometer; the junctions of the pile are too deep, and short-circuit the current; the bars too long and resisting, as well as too numerous; the junctions too slender; the mass of matter to be heated too great. These defects are remedied by placing the bars in glass tubes connected with these plates of copper; making the bars half the usual length, and using only a single pair. The defects in the galvanometer are that the wire does not come near the needle; the needles are not of the best form, and the suspension is troublesome. Mr. Ridout makes the wire a flat ribbon mounted on one bobbin; the needles are flat oblong plates from the same piece of steel, and magnetised in one piece; they are mounted on a pivot turning in an agate cup. The several parts of the apparatus are mutually adapted to each other; and in using it the galvanometer is not joined to the pile till the latter has been exposed to the heat, so as to prevent the current generated abstracting heat from the hot side. As made by Mr. Browning, the pile consists of a pair of elements $\frac{1}{2}$ in. long, the copper connections being circular plates $\frac{1}{16}$ in. thick and $\frac{3}{8}$ in. diameter. The pile is supported by thick copper terminals

above the galvanometer, which consists of a copper ribbon making some twenty turns round a pair of astatic needles 1m. long and ⅛ in. broad, pivoted in an agate cup. A contact-key is placed on one side, and the whole is inclosed in a glass shade perforated opposite the pile. A glass cone protects the front from extraneous heat, and a glass case the back. A directing magnet is fixed above the pile. Contact between the galvanometer and pile is made after (say) 30 seconds' exposure to the heat. The pile is affected by a person standing six feet from it, and the radiation from stellar space is evident in clear weather. Half a minute is sufficient to put the instrument ready for use.—Mr. Ridout also exhibited laboratory experiments showing cohesion in mercury by causing it to overflow up an inclined trough; *electrolysis of water by a single Grove or bichromate cell*, through diminishing the pressure in the flask containing the water by boiling it and condensing the vapour on cooling; a *differential thermometer showing absorption of heat on liquefying solids*; and the production of musical notes in glass tubes by contracting the bore smoothly to about ¼ of the diameter at one part. Prof. Foster remarked that the cohesion experiment might show the surface-tension. Prof. Guthrie and Prof. Hughes offered remarks on the electrolytic experiment, the latter stating that he finds the resistance of an iron cell he has constructed to depend on the electrodes rather than the liquid; when the negative plate is tempered iron the resistance is low, when soft iron it is high.—Prof. Stone exhibited photographs of König's new tonometer described by him at the last meeting, and further mentioned that König had devised a thermometer based on the principle that changes of temperature produce corresponding changes in the vibration rate of a tuning-fork. The temperature is found from the rate of the fork by bringing it to a zero rate by means of a rider.—Prof. Michin then described his experiment to solve the problem of transmitting light by photo-electric action. Two years ago he conceived the idea of employing for this purpose the fact that light falling on a sensitised silver plate disengages electricity. He forms a sensitive cell composed of two silver plates immersed in a conducting solution; one plate is coated with a sensitive emulsion of chloride or bromide of silver. When chloride is used, a solution of salt in water forms the liquid; when bromide, a solution of bromide of potash. A current is set up in the cell even in the dark, but when exposed to the magnesium light the current is very powerful, and flows within the cell from the uncoated to the sensitised plate. Prof. Michin also conducted this current by wire to a second cell in a dark chamber, and found that it effected a decomposition of the sensitive plate in that cell, as shown by a distinct darkening of the plate when "developed" by pyrogallic acid. The same effect was produced whether the current was reversed or not. Prof. Michin is continuing his experiments, and has provided a cable containing a number of separate conductors insulated from each other, in order to convey the currents from several cells. Prof. Perry feared that the effect would not be strong enough; but Prof. Michin said the light of a match produced a decided photo-electric effect in the cell. Prof. Perry alluded to the selenium plan proposed by himself and Prof. Ayrton, and said that Mr. Willoughby Smith had observed selenium to be sensitive to the shadow of a flying swallow. Prof. Adams testified to the sensitiveness of selenium and its power of being directly excited by light, a fact first proved by the experiments of Mr. Day and himself.

Entomological Society, April 7.—H. T. Stainton, F.R.S., vice-president, in the chair.—Messrs. G. C. Bignell, W. D. Cansdale, Frank Crisp, and the Rev. W. Fowler, were elected Ordinary Members, and M. E. André a Foreign Member.—Mr. J. T. Carrington exhibited a pale variety of *Arctia caja* which was bred by a gentleman at Croydon, who had been experimenting upon the effects of the rays of light transmitted through glasses of various colours upon this species. The specimen exhibited had been reared under green glass, but there was no evidence to show that the variation was due to the green rays.—The Secretary read a communication from Mr. Rothney, of Calcutta, on insects destroyed by flowers, with reference to a note on this subject published in the *Proceedings* of last year by Mr. J. W. Slater.—The following papers were read:—Notes on the coloration and development of insects, by Peter Cameron; on two gynandromorphous specimens of *Cirrochroa aoris*, Dbl., an Indian species of nymphalideous butterflies; and on *Cetonia aurata* and *Protactia bensoni*, by Prof. Westwood. Specimens and drawings were exhibited in illustration of the last paper, showing the specific distinctness of the insects in question.

Meteorological Society, April 21.—Mr. G. J. Symons, F.R.S., president, in the chair.—Rev. J. O. Bevan, M.A., F. E. Cobb, E. Filliter, F.G.S., T. L. Gentles, W. A. Harrison, F.R.G.S., J. W. Peggs, F. Slade, and E. J. C. Smith, were elected Fellows of the Society.—The discussion on Mr. Ellis's paper, on the Greenwich sunshine records, 1876-80, was resumed and concluded.—The following papers were read:—On the rate at which barometric changes traverse the British Isles, by G. M. Whipple, B.Sc., F.R.A.S., F.M.S.—A new form of Six's self-registering thermometer, by J. W. Zambra, F.M.S.

EDINBURGH

Royal Society, April 5.—Sir Wyville Thomson, vice-president, in the chair.—Mr. John Murray, of the *Challenger* Expedition, occupied the evening with an interesting and exhaustive paper on the structure and mode of origin of coral reefs and islands. After detailing the well-known and widely-accepted theory of Darwin, Mr. Murray proceeded to take exception to its general truth, and to substitute a new theory, which, in the light of the recent discoveries of the *Challenger* Expedition, appeared at once simpler and more consistent with the facts. The main features of this theory were as follows: The abundant pelagic life of the ocean was stated to be the chief food of the reef-building corals and of the deep-sea animals. Lime-secreting creatures were especially abundant in tropical oceanic waters. Tow-net experiments showed that in a cubic mass of the ocean one mile square by 100 fathoms, there were about sixteen tons of carbonate of lime in the form of calcareous Algæ, Foraminifera, pelagic Molluscs, &c. Although so abundant on or near the surface the dead shells of these organisms were quite absent from by far the greater part of the floor of the ocean. In all the greater depths they were removed during their fall or shortly after reaching the bottom by the action of carbonic acid, which was especially abundant in deep sea water. Other things being equal, they were found at greater depths where they were most abundant at the surface. On submarine elevations (which were probably all of volcanic origin) these dead shells were met with in great abundance: when the depth was less than a mile the shells and skeletons of almost every surface creature were present in the deposit. Mixed up with these we had in these deposits the shells and skeletons of deep-sea animals, as Echinoderms, Annelids, Polyzoa, Foraminifera, Corals, &c. In these more or less shallow depths the accumulation was relatively rapid, and the solvent action of sea water had consequently little effect. Eventually this bank reached near enough the surface to serve as a foundation for reef-building corals. As these corals built up to the surface those situated towards the outer margin of the coral plantation had a great advantage in the more abundant supply of food, and reached the surface first. If the coral-field or plantation were small (less than a square mile) the periphery was relatively large over which food came from the ocean, and from which detritus was carried to the interior; hence the interior was filled up and no lagoon was formed. The same was the case when the coral plantation was long and narrow. In larger coral-fields—the area increasing as the square and the periphery only in an arithmetic progression—*the interior parts of the coral plantation were at a relatively* great disadvantage, less food and less detritus for filling up were supplied per square mile, and in consequence a lagoon was formed. The carbonic acid in the sea water removed in solution the lime of the dead coral and coral rock from the lagoon. As the atoll extended seawards the lagoon was widened and deepened by the solvent and disintegrating power of the sea water. The structure of upraised coral atolls were referred to as confirming these views. Barrier reefs were explained on the same principles. Fringing reefs built seawards on a talus formed of their own *débris* and of surface shells and deep-sea shells and skeletons. A lagoon-channel was gradually formed by the solvent action of the sea water thrown over the reef at each tide. In this way the fringing reef became a barrier reef. Numerous sections of the reefs at Tahiti, from the survey of Lieut. Swire, of the *Challenger*, were exhibited. The structure of the interior overhanging reefs, and of the steep exterior submarine talus, were especially pointed out and explained. The chief features of barrier reefs and atolls were quite independent of subsidence, and would exist alike in stationary areas or in areas either of slow elevation or of slow subsidence. Throughout the volcanic islands of the great oceans the evidence of recent elevation was everywhere conspicuous, and the same was the case in regions of barrier

reefs and atolls, as shown by Dana, Jukes, Couthouy, Semper, and others. He would expect to find local areas of subsidence in the great ocean basins on either side of volcanic islands and atolls, and this is what the soundings of the *Challenger* and *Tuscarora* seem to show. On the other hand the lines of volcanic islands and coral islands had probably always been the sites of a gradual elevation, *for it must be remembered that these last* have probably almost all a volcanic basis. In all cases the great agencies are the growth of the coral where most nourishment is to be had, and its death and disintegration by the action of the sea at those parts which cannot be, on account of their situation, sufficiently supplied with nourishment. In many cases, however, this disintegration, by breaking up the reef, serves to so alter conditions that decaying parts get a new lease of life, and growth begins afresh where decay was formerly manifest. Mr. Murray applied his theory with singular success to the discussion of particular cases of coral islands, such as the Maldive Islands, the Chagos Archipelago, and the great barrier reefs of Australia. The special merit of the theory is that it does away with the great and general subsidences which is the peculiar feature of Mr. Darwin's theory. Of such subsidences there is no other evidence. These views were also in harmony with Dana's as to the great antiquity of the ocean basins. In a previous paper he had shown that a study of deep-sea deposits also argued for the permanency and great antiquity of these great ocean depressions. The co-existence of fringing and barrier reefs and of atolls in close proximity (*e.g.* in the Fiji Islands), which is not easily explained by Darwin's theory, offers no difficulty whatever when looked at in the light of Mr. Murray's principles. In the criticism which followed, Sir Wyville Thomson and Prof. Geikie spoke in terms of high commendation of the thoroughness which characterised Mr. Murray's paper, and the success with which he had been able to do away with the assumption which was the basis of Darwin's theory, but for the truth of which there was no positive evidence.

Paris

Academy of Sciences, April 26.—M. Edm. Becquerel in the chair.—The following papers were read:—On the inverse problem of the motion of a material point on a surface of revolution, by M. Resal.—On the law of distribution, according to altitude, of the substance in the atmosphere absorbing ultra-violet solar radiations, by M. Cornu. The identity of this law (which he is able to determine very definitely) with the barometric formula, shows that the absorption is exercised by the gaseous mass and not by aqueous vapour or dust, which leads to different progressions.—Study of the explosive properties of fulminate of mercury, by MM. Berthelot and Vieille. It is simply decomposed into carbonic oxide, nitrogen, and mercury. The authors furnish data of the heat liberated, the density, and the pressures developed in a closed vessel. The superior force of the fulminate is attributed to the almost instantaneous nature of its decomposition by simple inflammation, the almost total absence of dissociation of the products, and the great density of the matter.—On the cholera of fowls; studies of the conditions of non-recurrence of the malady, and some others of its characters, by M. Pasteur. The aliments suited to the life of the microbe in the fowl disappear in consequence of inoculation with attenuated virus.—Observations of Schaberle's comet at Marseilles Observatory, by M. Stephan.—On the meteorite which fell on May 10, 1879, near Estherville (Emmet Co., Iowa, U.S.), by Prof. J. Lawrence Smith. He thinks this meteorite should be placed apart for the phenomena of its fall, especially the force of penetration of its fragments into the ground, and for the mode of association of its mineral constituents.—On winter barley as forage, by MM. Pierre and Lemetayer. It is rather the abundance and precocity of this cereal which renders it in demand, than its richness in azotised matter.—On appointment of a scientific commission for the Panama scheme. M. de Lesseps specified documents he would give them. The work in hand came to this: 75,000,000 cubic metres to be excavated; 8,000 workmen for six years; 250 working days each year, or 1,500 days, during which 50,000 cubic metres should be done each day.—*Apropos* of M. Bouty's note on thermo-electric currents from a metal and a liquid, M. Du Moncel recalled former experiments by M. Hellesen and himself.—Some considerations in support of a note of March 29 on the impossibility of supposing in general a function of velocities in every question of hydraulics where frictions have a notable *rôle*, by M. Boussinesq.—On the dependence of two electromagnetic gyroscopes submitted to the same circuit of induction, by M. de Fonvielle. The velocity of each movable piece is diminished.—The death of M. de Luca was announced.—The surface of the wave considered as a limiting surface, by M. Mannheim.—On the numerical calculation of definite integrals, by M. Baillard.—On simultaneous linear equations and on a class of non-plane curves, by M. Picard.—On the series $F_2\ (\alpha, \alpha', \beta, \beta', \gamma, x, y)$, by M. Appell.—Influence of temperature on the duration of period of a tuning-fork, by M. Mercadier. He corrects a numerical mistake in his memoir as quoted by Wiedemann (with whom he is in agreement).—On the theory of induction-currents, by M. Mascart.—On an experimental method fitted to determine the lines of surface in stationary flow of electricity through conducting surfaces, by M. Guébhard. At a short distance from a thin plate of metal in a mixed solution of acetate of lead and acetate of copper, are held the free ends of two conductors connected with a pile; thus a double system of Nobili's rings is produced of remarkable constancy and regularity, and in relation to the positions of the electrodes and the contour of the conducting surface.—Absolute measurement of Peltier's phenomenon on contact of a metal and its solution, by M. Bouty.—Measurement of the difference of potential of two metals in contact, by M. Pellat. The method (which has precision exceeding $\frac{1}{100}$ Daniell) is one of compensation, and its principle is, that if two metals, A and B, are connected by a metallic wire they take the same difference of potential as if they had been put directly in contact. The author studies the effects of varied surfaces of metals, change of temperature, and influence of gases round the plates.—On the theory of double circular refraction, by M. Gouy.—Influence of temperature on the compressibility of gases under strong pressures, by M. Amagat. When a gas is $\left\{\begin{matrix}\text{more}\\ \text{less}\end{matrix}\right\}$ compressible than according to Mariotte's law, its compressiblity $\left\{\begin{matrix}\text{decreases}\\ \text{increases}\end{matrix}\right\}$ with the temperature.—Researches on the passivity of iron (second part), by M. Varenne. *Inter alia*, an iron rod may be made passive by immersion of only a fraction of it in concentrated nitric acid, and passivity may be produced by prolonged immersion of iron in compressed bioxide of nitrogen.—On the proportion of iron in mineral waters of Rouen and Forges-les-Eaux, by M. Houzeau.—Isomers of phloroglucine, by M. Gautier.—On the products contained in coke of petroleum, by MM. Prunier and Varenne.—On a singular explosion produced during heating of wine, and on a new mode of determination of alcohol, by M. Wartha. This explosion was probably caused by inflammation of a mixture of alcohol and air in the tun. M. Wartha is seeking to determine the limit of explosion of such mixtures.—Synthetic reproduction of the aluminous silicates and alkaline silico-aluminates of nature, by M. Meunier.—On the origin and development of the egg in the Medusa Eucope before fecundation, by M. Merejkowsky.—On the apparent analogies between cholera of fowls and the malady of sleep (nelavan), by M. Talmy.

MIGRATORY BIRDS AT LIGHTHOUSES

CONSIDERING the amount of nonsense that has been written and still continues to be written—in season and out of season—on the subject of the migration of birds, it is very refreshing to find two gentlemen in this country seriously setting to work to accumulate facts, which may in time be reasonably expected to enable ornithologists to arrive at an opinion, more decided than anybody can be said to possess at the present moment, with regard to that wonderful movement. It might be thought, perhaps, that we indeed had already enough and to spare of recorded observations, for lists of the arrival of migratory birds abound in most of our natural-history periodicals, to say nothing of provincial newspapers; but it does not require much study and comparison of those lists to perceive that, with some honourable exceptions, they are obviously the work of persons not at all fitted—whether by character, training, or opportunities it matters not—to be competent observers, and consequently the records of their observations have done uncommonly little to advance our knowledge of the subject. Every one who has tried anything of the sort must admit, if he speaks the truth, that the difficulties in the way of observing the movements of birds are much greater than at first sight would appear to be the case. To carry on this kind of systematic observation to any good purpose, a man, if he cannot make it his first object, must yet have such occupations as will not interfere with his being in the right place at the right moment, and of course the ordinary engagements of life are very apt to act as disturbing forces and to baffle his best intentions. Farmers, in the pursuit of their vocation, are perhaps of all professional men the most suited for the work; but the farmer may have to attend a couple of distant market-towns for as many days in the week, and unless his road thither and thence lies favourably, these will be *dies non* so far as his opportunities of observation are concerned. A very few years' experience will convince any sensible person that the first wheatear of the season is almost always to be seen on a certain down or heath, and the earliest swallow over a certain pool or reach of a river. Localities like these, once discovered, have to be watched daily by him who wishes to record faithfully the arrival in his district of those particular species, and the same is to be said of others. Even the most enthusiastic sportsman may be hindered by a score of circumstances over which he has no control from visiting for a week or more the particular spot in a copse or corner of a bog where, if there be a woodcock or a snipe in the country, he knows it is sure to be found. Seeing then that of the various kinds of out-door observations few are more subject to the accidents which affect human actions and habits than those which relate to the movements of birds, the extremely unsatisfactory nature of records made in what is at best a casual way may be accounted for, and hitherto we have had scarcely any records of any other sort.

Some time ago it occurred to Mr. Cordeaux, author of that excellent little book "The Birds of the Humber District," noticed in these columns some seven or eight years since (NATURE, vol. viii. p. 100), and to Mr. Harvie Brown, a gentleman not less well known by his ornithological writings, that a great increase in our knowledge of the subject would accrue if they could but get the keepers of the numerous lighthouses and lightships along our coast to assist in the work, and accordingly they set about enlisting these men in the service.[1] We know not whether these gentlemen had fully appreciated the unsatisfactory nature of existing records, upon which we have just been dwelling, nor does it signify in the least. It was evident to them, and might have been to others, that men who were always on duty and always on the look-out would be able, if so minded and properly instructed, to give valuable aid, and that their observations would necessarily be of a kind that it was impossible for any other class of people to make, for they would be carried on at hours when nearly all the rest of the world was indoors, if not asleep, and at places at once the most favourable and the most inaccessible to any one else.

By what steps Messrs. Cordeaux and Brown proceeded, and how they overcame the scruples (if any were entertained) of the authorities of the Trinity House Board in England and of the Commissioners of Northern Lights in Scotland, we are not told; but these gentlemen have to be congratulated on the result they have attained, which appears in the form of a most instructive and interesting "Report"—the first, we hope, of a long series—"on the Migration of Birds in the Autumn of 1879," printed in the *Zoologist* for the current month, to which we beg leave to call our readers' best attention. It appears that forms of inquiry and letters of instruction were sent to various lighthouses and lightships. To begin with the east coast of Great Britain, it is said that such papers were forwarded to *twenty-six* Scottish lighthouses, from *thirteen*, or just one-half, of which returns have been received, the remaining thirteen having either sent back the forms blank, owing to the unusual scarcity of birds last autumn, or having taken no notice of the request to fill them up. The same course was pursued with respect to *thirty-seven* English stations, from *twenty-five* of which returns have been received. On the west coast appeal was made to *thirty-four* Scottish stations, *twenty-four* of which replied, and to three on the Isle of Man (the Manxmen were silent), but to none in England or Wales. So much willing co-operation, we confess, we could hardly have anticipated, especially on a first experiment, and it certainly appears from the intelligent remarks (of which specimens are occasionally given by the reporters), in addition to the mere filling up of the sheets supplied to them, that the men must have taken considerable interest in the inquiry, as well as have taken no common pains in giving the information sought.

To form any conclusions on insufficient premisses is a rank offence in science, and it would be absurd to suppose that this single report throws any light on the mysteries of migration. But we are greatly mistaken if

[1] We give all credit to these gentlemen for the *originality of action*, but the conception of some such scheme had been taken up before. Among the numerous inquiries in which Mr. J. H. Gurney, jun., had engaged himself, he had already made some endeavours in this direction, and we are in a position to say that even prior to his time, though nothing came of it, the idea had been broached informally among some zoological members of the British Association for the Advancement of Science. Of this fact we, however, believe that Messrs. Brown and Cordeaux were not conscious, as indeed it could hardly happen that they should be.

some of them may not be cleared up by a series of such reports, and the chief value of the present successful attempt is, in our humble opinion, to show that the plan put into operation by Messrs. Cordeaux and Brown is workable, and we sincerely trust that they will continue their enterprising efforts. The amount of correspondence and trouble it must give them cannot fail to be very great, but they, as well as the lighthouse and lightship keepers, will have one kind of reward, and that, perhaps, one not altogether unsatisfactory. They will obtain the true gratitude of all ornithologists who believe in ornithology as a study of life, and we believe will receive from ornithologists without exception the credit and encouragement they so richly deserve. If the scheme can be kept going for half-a-dozen years we can scarcely fail to be in a position to know something worth knowing of the

> . . . . "wild birds that change
> Their season in the night, and wail their way
> From cloud to cloud," . . . .

whose movements at present give rise to so much speculation, and thereby, perhaps, penetrate another, and certainly one of the most interesting of nature's secrets.

THE RIVER OF GOLDEN SAND

The River of Golden Sand. By Capt. William Gill, R.E. With an Introductory Essay by Col. Henry Yule, C.B., R.E. (London: John Murray, Albemarle Street, 1880.)

"THE River of Golden Sand," the narrative of a journey through China and Eastern Tibet to Burmah, is likely to prove one of the most valuable books of travel that have been published for a considerable time. It is prefaced by a long and able introductory essay by Col. Yule. In it are indicated many points of geographical interest in the country in which the River of Golden Sand is taken as the axis—the part of Eastern Tibet which intervenes between India and China—and the history sketched of explorations in this extent of country previous to Capt. Gill's. This essay is so full of interest and information that we shall try to give a summary of the facts detailed in it.

The first thing that strikes an observant eye in looking at a map of Asia is the number of great rivers that rush southward in parallel courses within a very narrow space of longitude. This forms the most striking characteristic of the country between India and China. The first of these rivers, beginning at the west, is the Subanshiri, coming from the Himalaya and entering the valley of Assam. The next is the Dihong, which joins the Lohit—Brahmaputra proper—at Sadiya. The third river is the Dibong, which joins the Dihong before its union with the Brahmaputra. It is now believed that this does not come from Tibet. The people of Upper Tibet say they have only two rivers coming from Tibet—the Dihong and the Brahmaputra. The Brahmaputra enters Assam at the Pool of Brahma. This, from a curious piece of evidence given by Col. Yule, is evidently identical with Kenpu of Chinese geographers. The Ku-ts-Kiang is almost certainly a source of the Irawadi. The remotest sources of this river do not lie further north than 30° at the utmost. Its length is considerably shorter than the River of Golden Sand. The Mekong has its source in the far north of Tibet. Its lower course has only been known accurately since the French expedition. But the town of Tsiamdo, standing between its two main branches about latitude 30° 45′, was visited by missionaries in 1866, so that its course is known as far north as this.

The Chin-Sha, from which Capt. Gill's book takes its name, is, if not the greatest river in Asia, the longest. Capt. Gill followed the windings of this river, with a few digressions, during twenty-four marches on his way from Bat'ang to Ta-li-fu. This great river has its source in about 90° longitude—almost as far west as Calcutta. At this part of its course its channel is 750 feet wide, and the whole river from bank to bank nearly a mile wide. Flowing into China, it receives the name of Kin-Sha-Kiang, which it retains until joined by the Min, coming from Ssu-ch'uan. There it becomes navigable to the sea. The navigation has often many hindrances in the way of rapids and gorges. Capt. Gill was the first to give us any accurate knowledge of the Yun-nan and Tibetan part of this great river.

The remaining two parallel rivers are the Ya-lung-Kiang and the Min-Kiang. Capt. Gill is the only traveller that has traced the latter river to the alpine highlands.

How to obtain direct communication between India and China has always been a difficult problem. India first became known to China not across the mountains and through the river valleys, but by the enormous circuit of Bactria and Kabul. In the year 127 B.C., Chang-Rien, a military leader, in exploring the country round the Oxus, brought back a report of a land called Shin-tu, *i.e.* Hindu, India. Attempts were made several times to penetrate by the Ssŭ-ch'uan frontier to India, but with little success. Two hundred years later, when communication opened with India, it was by way of Bactria, and went on so for centuries. In the "Periplus," a work of the first century A.D., mention is made of trade in silk stuffs through Bactria to Bhrōch. Marco Polo, when making his way to the frontier of Burma, went by the same route as Capt. Gill on his ninth march from Ch-eng-tu. Ta-li-fu, which is so often spoken of in Capt. Gill's book, is a central point on the Chinese frontier. For centuries it has been the centre of all military and commercial communication between China and Burmah.

By the treaty of Tien-tsing British subjects received the right to travel in the interior of China. Modern exploration dates from this, and our knowledge of the physical geography, natural resources of the country, and characteristics of the people of China have been slowly growing. It must not be forgotten that the missionaries of the Roman Church travelled much over China and Tibet. Publicity would have been against their purpose, and geographical research was not their object, so that their journals came before a limited few. Abbé Huc, in his famous story of his journey with Gabet, gave the first picture of Eastern Tibet in modern times in 1850. Carl Ritter's great work, which appeared many years before Huc's, gives a great deal of information of the great road by Ch'eng-tu to Lhassa. Apart from the little known efforts of the Roman Catholic missionaries, no attempt was made to penetrate those regions until 1861. Blakiston's exploration of the Upper Yang-tzu, after the treaty of Tien-tsing, was the first in this direction. In 1867 the great French expedition to Ta-li under Garnier was made. This was the first time that any European

traveller (not a priest) had seen the Yachi of Marco Polo since he himself was there in 1283. In 1860 Mr. Cooper traversed from Han-kow to Bat'ang over the high plateau, the scene of Capt. Gill's expedition afterwards. Cooper hoped to reach India by China, but on the Chinese frontier his party had to stop their journey owing to the disturbed state of the country. There was not much geographical information collected on this journey. In 1872, Baron Richthofen at Ch-eng-tu was on one of those important journeys which forms the groundwork of Capt. Gill's work. His project came to an untimely end. In speaking incidentally of the labours of the Roman Catholic missionaries, Abbé Desgodins must not be forgotten.

In 1873 Augustus Margary was appointed to explore the country between the Irawadi and China. He successfully reached Bhamo from China, but on his return journey he met his tragic end. Since that time there has been a more recent journey made by Mr. Baber by a new route to Ta-chien-lu.

Capt. Gill's first journey was through the north of Pe-chih-li to the sea terminus of the Great Wall. His ascent of the Yang-tzŭ is full of interest. The greatest importance attaches to his journeys when he commenced his excursion from Ching-tu to the Northern Alps, to where the Chinese Kiang flows southwards into Ssŭ-ch'-uan. It was at this time that Capt. Gill came among highland tribes called Man-tzu and Si-fau. The people along the westward frontier are named by the Chinese Lolo, Man-tzŭ, Si-fu, and Tibetan. The Chinese look upon the Man-tzu as descendants of the old inhabitants of Ssŭ-ch'uan. Man-tzu and Si-fau are ambiguously used. Si-fau is used in Capt. Gill's book as applied to a Tibetan-speaking race in the north-east of Tibet.

Capt. Gill had meant to make a journey through Kansuh to Kashgaria, and from that through the Russian dominions to Europe. This plan was rendered impracticable by the unsettled state of affairs between England and Russia. His homeward route was the same that Cooper had tried nine years before by Lit'ang, Bat'ang, and Ta-li. He left Ch'eng for England by the Irrawadi on July 10, 1877. The first important place reached was Ya-chau. It is here that the trade of Tibet begins, brick tea or cake tea being the staple of the trade. Capt. Gill gives interesting details about this, and also of a similar manufacture at Hankow for Mangolia. English rupees have become the currency in Tibet. They have superseded the tea bricks which were formerly used as money. The great drawback to the tea trade in Western Tibet does not lie in the Chinese being unwilling to open the landward frontier, but in the jealousy of the Lamas. Their chief desire is to monopolise power, enlightenment, and trade.

Capt. Gill's second place of landing was Ch-eng-tu, the Chinese gate of Tibet, on the Ssŭ-ch'uan frontier. Very little is known of the ethnography of the tribes on the mountain frontier of China, Burma, and Tibet. The two most prominent are the Mossos and the Lisus. They have some claims to civilisation. The men are quite Chinese in appearance, and have adopted the dress and the pigtail. The women retain a fashion analogous to the fashions of the Swiss and Pyrenean valleys. Their vocabularies have 70 per cent. words common to both, and show a connection with some of the Burmese.

Capt. Gill has given a remarkable manuscript to the British Museum. Its hieroglyphical characters are unknown. It consists of eighteen pages about 9½ inches by 3½, each page having three lines, and the characters reading from right to left. The groups of characters are divided by vertical lines. Some of them resemble the old Chinese characters called Chuen-tzu. M. Terrier has in his possession another manuscript resembling this one, but probably Capt. Gill's one is much older. Garnier, while in Hu-nan, was told that in some caves near that province were found chests containing books written in European characters. Probably they may have been books belonging to extinct aborigines in phonetic characters.

The introductory essay, written by so high an authority as Col. Yule, will greatly enhance the value of Capt. Gill's work.

The work is in the form of a journal, and is so graphically written that throughout the interest never flags. The account of the journey through the north of China is full of information regarding the physical aspect of the country and the many beautiful scenes Capt. Gill passed through. Pekin, it appears, is much the same as in the time of Marco Polo, but a great deal of its former grandeur seems to have gone. That 300,000,000 of people should have remained unchanged for centuries seems a very extraordinary fact. Yet in whatever part of the world the Chinese are found they still retain the individuality of their race, and act in all things as their forefathers did hundreds of years before. Their lack of imagination and love of independence, Capt. Gill thinks, account greatly for their stagnation. If the Chinese ever had any originality, perhaps the worship of antiquity and the system of examination have had something to do with eradicating it.

The voyage along the Chin-Sha-Chiang was full of surprises; the scenery was constantly changing. At one time the river went winding through "great plains where broad lagoons lay stretching out amongst fields that were protected from the summer floods by extensive dykes and embankments." Now the grand river, clear and almost green, rolled below cliffs of red sandstone. Beyond Ch'ang "the river narrows from 400 to 500 yards. Steep spurs from the mountains 3,000 feet high run down to the water's edge, their sides, wherever not absolutely perpendicular, covered with long, orange, brown grass, that seems to grow almost without soil. On the more gentle slopes terrace cultivation is carried on. Little patches of the most brilliant green, sometimes a thousand feet above the river, show the presence of some industrious farmer who will not leave a square yard uncultivated if he can help it." "The Chinese," Capt. Gill says, after speaking of their great industry, "plough about as well as the natives of India, doing little more than scratch the ground. It is true they raise two crops on the same field, as, for instance, when they plant opium under rape, or yams under millet. They have no knowledge of the modes of improvement practised in the various breeds of cattle; no instruments for breaking up and preparing waste land; no system for draining and reclaiming swamps and morasses." On the banks of this river Capt. Gill saw flowers being picked from a tree like an apricot-tree. The blossoms were like long conical-shaped pods; on their surface were numerous

small flowers full of pollen. The poor people make a drink from these instead of tea. This flower could not be identified, although high botanical authorities were consulted.

The Chinese could not understand why any one should travel in discomfort when he could stop at home in ease. They cherish the most profound respect for any literary person, so to explain his incomprehensible habit of looking at everything, Capt. Gill went about with a note-book in his hand, telling them he was going to write a book. He came on many villages whose original inhabitants had been expelled by the Chinese, who still continue their advance, stopping only where the soil and the climate refuse fruits to those industrious agriculturists. Ch'eng-tu, where Capt. Gill made some considerable halt, has changed much since Marco Polo wrote his description of it. The same river still runs by the city, but not through it, as it did then. The large plain that incloses the town has gradually been drained. At one time it must have been the bottom of a lake. Many insect-trees were met with on the way to Tibet. "It is on this tree that the insect is bred that produces the white wax of Ssŭ-Ch'uan. The trees are something like willows. Here the insect emerges from his egg, and the branch of the tree on which he is placed is soon covered with a kind of white wax secreted. It is this white wax that is so celebrated, and is one of the most valuable products of Ssŭ-Ch'uan. These eggs cannot be exposed to the heat of the sun, and whilst being carried from the breeding to the producing district the coolies travel only in the night, when the road is said to present a very remarkable appearance, as they all carry lanterns. Ordinarily in China no travelling is done at night, and as the gates of all towns and cities are closed at dusk, and are never opened for anybody, no matter who he may be, travelling at night is rendered impossible. But during the time for bringing the eggs to Kia-Ting-Fu all the city gates are open night and day—probably the only exception in China to the rule of shutting the gates at dusk. The one day it seemed to Capt. Gill as if "the happy valley of Rasselas had been in Tibet," the next day he was driving through piercing cold. On his way to Batang he had a glorious view of Mount Neu-Da. "No words can describe the majestic grandeur of that mighty peak, whose giant mass of eternal snow and ice raises its glorious head seven thousand feet above the wondering traveller, who yet stands within five miles of its summit. He can but gaze with admiration and appreciate the feelings of the Tibetans that have led them to call it Neu-Da, or the Sacred Mountain."

The Lamas seem to be the great curse of Tibet. The scapegrace of a family goes into a Lamassery, not, however, entirely for devotion, coming home at short intervals for amusement. "The Lamas assist in no way in the maintenance of the State; their lands are free from taxation, and they do not pay one iota towards the Government expenses." The customs of the people of Tibet seem to resemble those of the Israelites. They pray on the house-tops, pay their cattle-keepers as Jacob did, and set before strangers "butter in a lordly dish." The population is diminishing in Tibet by the oppression of the Lamas and emigration to Yun-Nan. The land that the emigrants leave behind them goes to the Lamasseries. As it cannot be taxed the burden of taxation becomes heavier on the remaining people, who still have to make up the same amount.

At Shin-Ku Capt. Gill bade adieu to the River of Golden Sand and continued his route to Bhamo, in the footsteps of Marco Polo and Augustus Margary. He came on the scene of Margary's death. The most fitting tribute that could be paid to this brave officer was "to establish in those border-lands the right of Englishmen to travel unmolested."

Instead of a gigantic river like the Chin-Kiang, the Irawady above Bhamo, though wide, is very shallow. The continual rain that falls over its basin is very great. At Bhamo Capt. Gill was welcomed by Mr. Cooper, who in all his dangerous wanderings had escaped with his life; when safety seemed to come he fell by the hand of an assassin under the British flag. Capt. Gill's homeward journey was through New Mandalay.

Capt. Gill's book will prove a valuable authority on the particular part of China through which he travelled. It does not represent the scientific results, which were published in the *Journal* of the Royal Geographical Society. His journey in Western China is one of the most successful that has been made, although it was achieved under a great drawback; he did not know the Chinese language. He was, however, very fortunate in his two interpreters, but his success was due to his great tact and perseverance. He tells his story with a brightness and impressiveness not common in modern books of travel, and his originality and independence of view are evident in every page. He has no very great opinion of the Chinese, and his remarks on their peculiar characteristics are well worth consideration. One sees the born traveller in every entry in his journal; nothing is thrown in for effect. A great deal of his journey was made in the dark, through fog and rain, yet he adhered strictly to his rule of writing the accounts of the day's doings every night. This had often to be done with the comforting thought that most probably the record would be lost.

The work is well supplied with maps and illustrations, the former especially being among the most valuable of recent contributions to the hydrography of Asia.

OUR BOOK SHELF

The Geological Record for 1877. *An Account of Works on Geology, Mineralogy, and Palæontology published during the Year, with Supplements for* 1874–1876. Edited by William Whitaker, B.A., F.G.S., of the Geological Survey of England. (London: Taylor and Francis, 1880.)

We hail with pleasure the appearance of the fourth volume of this most valuable work. The indefatigable editor deserves all praise for the energy with which he has worked in getting together a staff of volunteers to compile the useful abstracts of contents of the numerous works and memoirs noticed in this volume of 432 pages. It is unfortunate that the work has now fallen two years into arrear, but, now that the staff of contributors seems to have fairly settled down to its work, we hope the editor will soon be able to recover lost time, and that each succeeding volume will appear within the year following that for which it is issued. The editor has been very happy in discovering a method by which the officers on the staff of the Geological Survey may

usefully employ their leisure, by contributing to geological literature, and we heartily wish him success in his work.

Ensayo sobre una nueva enfermedad del Olivo. Por Don Pablo Colvée. Publicado en la Gaceta Agricola del Ministerio de Fomento. Pp. 43, pl. i-ii. (Madrid, 1880.)

IT appears that the Spanish olive crop is being jeopardised in the neighbourhood of Valencia by an insect of the family *Coccidæ*, distinct from *Lecanium oleæ*, already known as attacking the olive, and considered by Don Pablo Colvée to be a new species of the genus *Aspidiotus*, which he describes as *A. oleæ*. It apparently attacks the tree generally, but especially the fruit, causing the full development of the latter to be arrested. The greater part of Don Colvée's paper is occupied by considerations on the development of insects in general, and on those attacking the olive in particular. The author appears to suggest no special remedy, but judiciously invites investigations as to whether the attacks of the insect are the primary cause of the want of health in the trees, or whether the latter does not invite the attacks.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Winter "Swallows"

SOME months ago I tried to investigate, so far as possible, the many recorded occurrences of swallows in this country in winter. As might be expected, a large proportion of them broke down on inquiry, but there was one which, for several reasons, I thought might be safely trusted. It appeared in the "Remarks on the Weather during the Quarter ending 31st of March, 1864" (p. 5), appended to the Registrar-General's Report for that period, and stands thus:—

"*Swallows were seen* on January 22d, three miles south of Grantham."

Through the kindness of Mr. Glaisher, F.R.S., and of Mr. Jeans of Grantham, I was at last put into communication with the original circulator of the statement, who obligingly wrote to me (omitting names) as follows:—

"——— Grantham, Sept. 23d, 1879

"SIR,—The information given to ——— respecting the swallows, I discovered some time afterwards was not correct; what was taken to be swallows were the common bat. I much regret being instrumental in incorrect statements being published; it was an Irishman in my employ who told me of them; he some time afterwards showed me what he supposed to be swallows.

"I remain, sir,

"Your obedient servant,

"——— ———"

I leave to others the moral that may be drawn from the above.

Does Chlorophyll Decompose Carbonic Acid?

I HAVE read with much interest in NATURE, vol. xxi. p. 557, Prof. Lankester's remarks on the question—Does Chlorophyll decompose Carbonic Acid? and having many years ago made experiments on that and kindred topics, should be much obliged if you will do me the favour to reprint the following extract from a paper I published in the *Philosophical Magazine* (December, 1872, p. 425, &c.). This is also in my scientific memoirs, p. 409, 410.

"The decomposition of carbonic acid by plants is undoubtedly the most important of all actino-chemical facts. The existence of the vegetable world, and, indeed, it may be said, the existence of all living things, depends upon it. I first effected this decomposition on the solar spectrum, as may be found in a memoir in the *Philosophical Magazine* (September, 1843). The results ascertained by me at that time from the direct spectrum experiment, that the decomposition of carbonic acid is effected by the less, not by the more refrangible rays, have been confirmed by all recent experimenters, who differ only as regards the exact position of the maximum. In the discussions that have arisen, this decomposition has often been incorrectly referred to the *green* parts of plants. Plants which have been caused to germinate and grow to a certain stage in darkness are etiolated, yet these, when brought into the sunlight, decompose carbonic acid, and *then* turn green. The chlorophyll thus produced is the effect of the decomposition, not its cause. Facts derived from the visible absorptive action of chlorophyll do not necessarily apply to the decomposition of carbonic acid. The curve of the production of chlorophyll, the curve of the destruction of chlorophyll, the curve of the visible absorption of chlorophyll, and the curve of the decomposition of carbonic acid are not all necessarily coincident. To confound them together, as is too frequently done, is to be led to incorrect conclusions."

Nothing can act before it exists, nothing can originate itself. Chlorophyll is therefore the result, not the cause, of the decomposition. Its continual increase during the life of a plant is an effect of the same kind. The force decomposing carbonic acid does not reside in chlorophyll, but elsewhere in the structure of the leaf.

On a Point Relating to Brain Dynamics

ANY attempt to grapple with the doctrine of Free Will *v.* Necessity on the old lines would probably (and deservedly so) not attract much attention. The object of this paper is to place a consideration of extreme simplicity under critical notice, which would seem to be capable of affording a key to the complete reconciliation of the divergent views on a common basis; and since the matter to be dealt with will be strictly within the domain of natural science, a clear analysis will be rendered possible.

It is well known that the only attempt to harmonise the doctrine of Free Will with the principle of the Conservation of Energy consists in supposing that living creatures have a power, by the mere exercise of their "will," of deflecting particles of matter within their bodies from their natural paths, without thereby altering the total energy of the particles.[1] This, therefore, it will be observed in the first instance, assumes a peculiar physical state of things to exist within the body of an animal which does not prevail elsewhere, or it supposes that the laws of nature have not a general application, but that the animal world must be made an exception. This at the very outset evidently involves a very questionable admission. My purpose is simply to point out that by taking into account a special consideration based on the evidence of modern physiology as to the functions of the brain, such an assumption as the above is rendered entirely superfluous, and that even if it could be supported it would still miss the main object in view.

Whatever room for speculation there may be as to the exact nature of the mental faculties, it is at least very generally admitted that these faculties are most intimately *connected* with or dependent on brain structure. Modern physiological research has at least placed this fact beyond question, or it is allowed that the mental faculties have at all events *a physical side*. From this it must follow therefore that what we call "identity," character, or individuality (as involved in "mind") must be dependent on the special structure of the brain; indeed this view is so widely prevalent that it becomes almost superfluous to insist upon it. Now it may be safely assumed that no upholder of Free Will would wish for more than that a person should act in strict accordance with his identity or individuality, for the object of Free Will certainly is not to annihilate individuality (or those personal *traits* which constitute character). But is not this precisely what would occur if this contention for a mysterious power of deflecting particles within the body could be carried out? for the effect of this contention would be to make the brain superfluous as a directing mechanism, which would be tantamount to abolishing it (together with the individuality, of

[1] The necessity for this special assumption, in order to prevent Free Will from coming into direct collision with the principle of the Conservation of Energy, is so obvious that it will probably be regarded as superfluous to give references to particular authors.

which it is the seat). For where would be the use of the elaborate mechanism of the brain for directing the movements of the body if we are to have power of carrying out this same object by deflecting particles by "volition" (whatever that may mean)? This would be to substitute for the brain, with which the identity is bound up, the empty nothing "volition." In that the brain directs the corporeal movements; the identity, or that which constitutes the very essence of individuality, thereby directs. What more would we have? Attempt to supplant the brain by the vague notion "volition," and the individuality ceases to exist; or that very end is attained which those who support Free Will most wish to avoid.

From the very fact that the brain is *known* to exist, it therefore should be perfectly conceivable (if not even *à priori* a natural conclusion) that the brain might be a mechanism competent to regulate all[1] the motions of the corporeal system (for a set of dynamical conditions adapted to *any* effect is conceivable). In view of this, does not the assumption of this mysterious "deflecting power" seem all the more unwarrantable, or even absurd; as if it were imagined that the brain, being already there to direct the corporeal movements, something additional were necessary to direct the brain, or as if it were supposed that [the brain being the seat of the identity] something besides the identity were required to direct the actions of the body? This would seem to be no more than a specimen of the kind of incongruities which may be expected to present themselves by any attempt to evade physical principles.

It could not, however, be said that the opposite party were entirely free from error. For there appears to have been a notable oversight on the side of those who uphold strict Causal Sequence in nature (sometimes called "Necessity") in failing to appreciate adequately the important influence (on the question of Free Will) of the fact that the brain is the seat of individuality, as above insisted on. For the omission to give due import to this fact has naturally made strict Causal Sequence to appear as a sort of grinding process, whereby man's actions are determined *independently* of his individuality; a view which is no doubt repulsive, and may have served as some excuse for the invention of the curious device of deflecting particles by the "mind" or "will." It will be observed, however, that by simply substituting the word "brain" (which includes "mind") for the word "mind" in the foregoing sentence, a deflection of particles of matter (represented by the direction of material operations by the brain) then can take place in accordance with and not in opposition to the laws of nature. For from the very fact of the brain substance forming part of the material universe it must of course influence and direct material operations in conformity with natural causes.

Could it be justly said that there is any *compulsion* in this? Can there be compulsion in being obliged to act in accordance with one's individuality or identity (determined by brain structure), since the only conceivable escape from this would be to act *in opposition* to one's identity (scarcely a desirable end)? But, it may be argued, there is still some coercion left here, because, although brain structure may be the seat of individuality or "mind," nevertheless, since our brains were originally formed by the operation of causes beyond our control, there is coercion in this aspect of the case. But then do even the most ardent supporters of Free Will ever dream of upholding the expectation that an individual should have a control in the original formation of his brain? or do they not concede (and rightly) that the ideal of Free Will is that an individual should act in strict accordance with (and not in opposition to) his own identity? Yet this is precisely what the believer in strict Causal Sequence, who has a just appreciation of the functions of the brain, will maintain must necessarily occur. Solely in virtue of the fact that there is strict Causal Sequence in nature are the actions brought into strict conformity with individual brain structures (or with identity). If the principles of dynamics were not rigid, or if the laws of nature were liable to alteration, a man's actions might sometimes be in harmony with his brain structure, sometimes in discord with it; or any number of persons, though possessing totally different brain structures, might act identically. The questionable expediency of the proceeding of those who are disposed to grumble at what they term the "iron" laws of nature, becomes apparent here.

But is it not, after all, more satisfactory to look to a definite physical basis for identity or idividuality, as dependent on the magnificent mechanism of the brain, in preference to the superficial view of ignoring all this? No doubt there have been misunderstandings on both sides of this Free Will *v.* Necessity question.—The Free Will party, failing to appreciate justly the sequence of cause and effect; the Necessitarians, on the other hand, omitting to realise fully the important bearing of the relation of individuality to brain-structure on this question. No logical ground could be given why a complete agreement should not be possible on this subject. For there can evidently be but *one* correct view on any subject or question whatever. Moreover, from the very fact of the fundamental character of this question, it would follow necessarily that the wrong view on this subject must involve a great error, which, therefore, could hardly escape detection under a careful analysis. The divergence of views here is, however, no doubt more apparent than real. For if Free Will may be justly regarded as the freedom to act in accordance with identity (or as the assertion of individuality), then such freedom of will actually exists, and moreover the very condition for its existence is seen to be the prevalence of that strict Causal Sequence in nature demanded by the Necessitarians. Thus the two views would show themselves capable of reconciliation on a common basis. That this fact should have apparently hitherto escaped appreciation may possibly be to some extent due to that spirit of partisanship which has so largely entered into this question, whereby the judgment may be allowed to be unconsciously biassed, so that in some cases, instead of searching impartially as to what *is* truth, the inquiry has perhaps rather been as to what *ought* to be truth.

London S. TOLVER PRESTON

[1] Does it not seem a violation of principle, or a kind of inconsistency, to recognise that the brain does, in fact, direct certain motions of the corporeal system (and even those of a complex character, such as the digestion of the food, the circulation, &c.), and yet to assume that the brain would be incompetent to direct *all* the motions of the body? It may be said that a reasoning process accompanies the direction of some of these motions, but not others. But then is not reasoning itself a brain process, or is it not universally admitted that the reasoning faculty (whatever its exact nature) is at least *connected with* the brain, or has a physical side, just as, indeed, the mental faculties generally (or "mind") could not exist without brain?

Curious Botanical Phenomenon

ABOUT a fortnight ago I noticed a curious phenomenon in a wood near Leyland, Lancashire. The ground was strewn with a layer of about eight to ten inches of old sodden leaves, covered at the surface by dry withered ones. A quantity of hyacinths (not yet in flower) were growing on this ground, and many of the plants had pierced through the withered leaves to the extent of from half an inch to three inches, carrying them up above the general surface. Some of the hyacinths had in this way penetrated through more than half a dozen withered leaves, and here and there several plants were gathered together at their tops by a number of old leaves, through which they had conjointly grown.

The question arises as to whether the hyacinth shoots had pierced through the withered leaves on first issuing from the ground, when the dead leaves were soft and wet, and so lifted the latter to the surface where they became dried, or whether they had actually pierced through the dry leaves on the surface.

Carboniferous Forest at Oldham

IT may perhaps be interesting to the readers of NATURE to know that here at Oldham we have recently laid bare a fine sample of a carboniferous forest. We are here, as you are aware, situated on the middle coal-measures, Oldham Edge (800 feet) being the highest outcrop of that series.

I have been watching with increasing interest during the past eighteen mouths the progress of disinterment. For some time at the commencement the trees occurred at considerable intervals of time, but of late they have turned up more frequently, scarcely a day now passing without one or more being unearthed. They are, I am sorry to say, highly perishable, and if the necessities of the works did not require their removal they would all disappear during a single winter if exposed to the weather.

The result of the combined action of the two great faults that cross Oldham in a direction parallel to each other has been to throw up to the surface several seams of coal and beds of shale and sandstone.

On the eastern escarpment of the "Edge" a quarry has been dug in the argillaceous shale above what is here known as the "Bent Mine," in order to make bricks of the extracted materials. In quarrying this bed the trees have been laid bare in considerable numbers. Some of them show the characteristic

markings of Sigillariæ, longitudinal flutings and the usual leaf-scars, stigmarian roots and rootlets attached, &c., others not so well preserved, being of doubtful affinities. Of course they are now but casts, nothing remaining of the original trees except a thin film of coaly matter representing the bark. They measure in height from three to ten feet, and have a diameter of from one foot to two feet four inches. I think it may be safely stated that they were merely hollow stumps when finally submerged, fronds of ferns, lepidodendroid twigs and leaves, and other vegetable waifs having found their way into the hollow cylinders and left their impress on the inclosed matrix.

I may add that there are several horizons of growth, one forest having grown above another; stigmarian roots and rootlets, calamites, lepidodendroid stems and leaves, lepidostrobi, and masses of leaves of unascertained species being indiscriminately mixed throughout the whole section, the ferns, however, being met with in greatest numbers near the bases of the erect trees.

It is perhaps worthy of remark, too, that there is no accumulation of coaly matter in the section revealed, nor is there any of the usual "floor clay" about the roots of the trees.

Fungus Inoculation for Insects

THE importance attributed by Dr. Lankester (NATURE, vol. xxi. p. 448) to "Prof. Metschnikoff's suggestion of a deliberate cultivation of an insect's-disease-producing fungus, and the application of the cultivated fungus in quantity to places infested by these insects," invites attention to the fact that the suggestion has been anticipated in a very serious and earnest way by my friend the distinguished entomologist, Dr. John L. Le Conte of Philadelphia, in his presidential address before the Portland meeting of the American Association for the Advancement of Science, in August, 1873.

His address concluded with ten suggestions for the promotion of economic entomology in the United States, and the seventh reads thus:—"Careful study of epidemic diseases of insects, especially those of a fungoid nature; and experiments on the most effective means of introducing and communicating such diseases at pleasure."

The reasons for making this suggestion are fully stated in the preceding paragraphs of the address, where the observations on which it is based are detailed.

Dr. Le Conte's first suggestion was, "Reorganisation of the Department of Agriculture [at Washington] on a scientific basis, for the proper protection and advancement of agricultural interests." Had this suggestion received the attention which has been given to many other subjects of less practical importance, the present reclamation for him of priority in the case of his seventh suggestion, would probably have been rendered unnecessary; and the credit of introducing a more reasonable method of extirpating insect-pests than the dangerous plan of distributing potent mineral poisons to careless or uneducated persons for use in the fields, would have been secured to the nation to which we have the honour to belong.

Dr. Le Conte's address may be found in the published volume of the *Proceedings* of the Portland meeting; but it was reprinted by him and extensively circulated and favourably commented upon at the time, his desire being precisely that so well expressed by Dr. Lankester "to do something to persuade 'practical' men that all science is deserving of their respect and encouragement." We all hoped that such earnest words from so high an authority would have their due effect upon Congress and inaugurate a long-desired reform of our Agricultural Bureau. But it has happened, as in so many other instances, that we have had to wait seven years before even an echo reaches us from a distant part of the world, where the labours of Prof. Metschnikoff have procured an intelligent appreciation of the value of Dr. Le Conte's suggestion, so little comprehended by the powers at home. Carnivorous Wasps

A SERIES of letters, under the above heading, have appeared in NATURE for several weeks past. The facts they contain, although interesting in themselves, are nothing new to entomologists. That wasps are carnivorous, that they chase flies, &c., was known long ago (compare Westwood's "Introd. to Entomol.," ii. p. 246). That wasps cut off the wings of flies before sucking them was observed by Dr. Erasmus Darwin in the last century (see J. H. Fabre, "Souvenirs Entomologiques," Paris, 1879). AN OLD ENTOMOLOGIST

Heidelberg, Germany, May 6

Seeing by Telegraphy

WE beg to thank Mr. Gordon for drawing attention to the fact that the principle of rotation of plane of polarisation of light in a magnetic field could not actually be employed with the form of receiver symbolically described by us in NATURE, vol. xxi. p. 589. Having satisfied ourselves that there could be no doubt of the feasibility of using the first form of apparatus, which we spoke of, as a receiver in a sight telegraph, we merely wished to point out, at the end of our letter, that other methods might perhaps be employed; and we still have no doubt that with a certain proper arrangement of the apparatus not only the effects observed by Dr. Kerr, but other of the Faraday polarisation of light effects might be practically made use of. For it must be remembered that the actual electric currents now used to transmit articulate speech are only one forty-millionth per cent. as strong as those necessary to work even a delicate telegraph relay, whereas it required several Grove's cells to show in a decided way the old experiment of the sound emitted by an iron bar on being magnetised.

And in fact we may go further, and mention that we have for the last year, or more, held the view that just as all electric conductors turn into heat energy a portion of the energy they transmit as electric current, so there must be some bodies, presumably of the sulphur selenium order, which, when properly employed, will convert a portion of the current energy into visible luminous vibrations, and may therefore be used as receivers in a sight telegraph.

As to the other objection that might have been made to the method as popularly described by us in consequence of the large number of wires, we need hardly mention that in practice a telegraph engineer would avail himself of the principles of multiple telegraphy. JOHN PERRY

May 3 W. E. AYRTON

Anchor-Ice

IN confirmation of Mr. Rae's views upon this subject, the following results of observations made upon the Charles River, Mass., may be of interest.

Anchor-ice is usually formed at night during a sudden "cold snap," when the river is not covered with surface-ice. It seems to consist of small masses of needle-like crystals grouped in stellate forms, and distributed pretty evenly throughout the body of water.

These adhere readily to any obstruction, and accumulate rapidly upon it. Thus the racks or strainers through which the water passes to the mills are covered and closed by it, so that the flow of the water is absolutely stopped, and the mills can only be kept running by constantly removing it with a rake.

It is very adhesive and tenacious. I have frequently seen it accumulate upon portions of the extreme edge of a mill dam (over which was pouring water a foot in depth) until it reached the surface, resisting for a considerable time the enormous pressure to which it was thus subjected. It usually disappears soon after sunrise.

Detached portions of the accumulated masses always rise to the surface, but the original crystals, if not heavier than water, seem to be at least as heavy. The general appearance of this ice when removed from the water resembles that of sherbet or "water ices." As these are frozen quickly while in motion, they are apparently formed under similar conditions. I have never seen anchor-ice except in rapid currents.

FURTHER OBSERVATIONS AND RESEARCHES ON FLEUSS'S SYSTEM OF DIVING AND LIVING IN IRRESPIRABLE ATMOSPHERES[1]

YOU will find in NATURE, vol. xxi. p. 62, the experiments I made in relation to the process of living under water by means of the Fleuss apparatus. I there related what I had observed after Mr. Fleuss had been under water at a very low temperature for the period of an hour. A few days later I made another observation on a different plan. I filled the large diving bell at the Polytechnic with carbonic acid gas, displacing every portion of air. I then let the bell go down ten inches under the water, so as to put the gas under pressure, and all the while I kept a stream of gas pouring into the bell, and causing a constant bubbling of gas out of the mouth of it into the water. This done, Mr. Fleuss put on his dress and helmet and entered the bell. He sat in it over the water for the period of twenty minutes, the pressure and constant stream of gas being maintained. At the end of twenty minutes I signalled to him to come out, and had the bell brought round to the side of the tank. He returned into the air quite unaffected. His pulse, which was beating at 72° in the minute when he went in, was at 68° when he came out, and quite steady. His temperature in the mouth, which was at 98·2° F. when he went in, was at 97·5° when he came out, and in a few minutes was at its natural standard. He said he had felt no oppression whatever, and would have remained an hour in the gas if I had allowed him.

While the diving-bell was still charged with a large volume of carbonic acid gas I got Mr. Fleuss to go into it again, and then volatised into the bell vapour of amyl hydride until I had made an utterly irrespirable atmosphere from that vapour alone. In this way I formed an atmosphere which closely resembled the atmosphere of the mine charged with choke-damp, except that the vapour I used is more determinate in its narcotising action than choke-damp. In this mixed atmosphere, in which a man unprotected would have been absolutely unconscious in less than a minute, Mr. Fleuss remained for twenty minutes. At that time he came out of the bell in the most perfect condition, in a word, altogether unaffected.

The principle of the Fleuss system is very simple. Within the helmet, which is of the usual shape of a diver's helmet, there is a space equal to a quarter of a cubic foot inclosed in metal. This space is charged with oxygen under pressure, the compression giving a supply of the gas sufficient to last for a period of five hours if necessary. As a rule Mr. Fleuss charges for three hours under a pressure of about eight atmospheres. This is his supply of vital air. In the cuirass, which is the next part of the apparatus to be described, he has two metal cases, one in front, the other at the back. These cases are filled with small pellets of porous india-rubber charged with caustic soda. Over this surface of soda he can exhale his breath with perfect freedom, and at the lower part of each case he has a small trough under a perforated bottom, in which the water of the breath, condensed in passing, is caught. Lastly, he has a double-valved mouthpiece, made almost exactly after the plan of the late Dr. Sibson's chloroform mouthpiece, to which is attached a large elastic artificial trachea, or windpipe.

These are the effective parts of the apparatus. The other parts, common to the diver's dress, are the waterproof jacket and leggings and weighted boots.

In preparing for his work Mr. Fleuss proceeds as you will see (for he will go step by step through the process of assuming his dress). He first charges his helmet with oxygen. He does this from one of Orchard's compressed oxygen bottles, measuring the pressure by a pressure-gauge. This ready, he puts on the cuirass and the waterproof dress. Then he ties firmly over his mouth and nostrils the double-valved mouthpiece, and connects the free end of the artificial windpipe with a tube leading into the soda-chamber in front of the cuirass. Finally he assumes the helmet, and when that is on and closed he is complete.

The mode in which he lives in this closed dress is as follows:—By a valvular opening he lets into the helmet from the compressed store of oxygen a stream of oxygen, which diffuses into the space between the helmet and cuirass and his body—his breathing- or air-space. When he inhales through the mouthpiece he draws in the oxygen through the two side valves into his lungs. When he exhales, those valves close, and so his exhaled breath passes through the tube and over the soda in the soda-chambers, and down the chamber in front along a connecting tube into the lower part of the chamber at the back; then, ascending through that chamber, it escapes *in part* into the helmet by a tube from the back chamber near the shoulder. In its passage through these two chambers all the carbonic acid of the breath is fixed by the soda, and most of the water is condensed in the troughs. The return oxygen and the nitrogen of the expired breath passes over free and enters the helmet, where it meets and admixes, by diffusion, with the oxygen which is admitted from the oxygen reservoir.

Thus there is constantly being made within the dress a fresh supply of air for respiration, while the product of respiration and of animal combustion—carbonic acid—which would be dangerous if it were not removed, is removed and fixed by the soda.

Mr. Fleuss relies on two practical indications for supply of the oxygen from the reservoir. If he feels any undue pressure on the drums of his ears he knows that there is too much oxygen in the helmet. If he feels any sense of suffocation he knows that the oxygen is deficient. In the first instance he stops the entrance of oxygen for a short time; in the second case he lets in a further supply.

It must be admitted that this plan is not one that ensures a due admixture of oxygen and of nitrogen according to the atmospheric formula, and there can be no doubt that he is always breathing, while in his dress, an excess of oxygen. This fact opens up the question once more of pure oxygen as a supporter of natural life.

In my experiments on this subject reported to the British Association for the Advancement of Science in 1860, I showed that oxygen supplied in steady current from a fresh source, and not breathed many times over again, would support life readily enough for long periods of time—extending in one experiment to three weeks—at a medium temperature; but that at a low temperature, 35° F., it became negative, so that animals went to sleep in it and became cold; while at a high temperature, 75°, they became heated in it, underwent rapid wasting, and ate voraciously.

In another paper, published in 1869, I tried to prove that the use of nitrogen in the atmosphere is not to act as a mere diluent and economiser, but as an equaliser of the temperature, and so to make the combination of oxygen with the blood and the tissues equable in the different regions of the globe.

Mr. Fleuss's experiments are in entire accord with these views. He can live, with oxygen in excess, for long periods in medium temperatures. In a cold temperature his own heat goes down several degrees below the standard. In a high temperature he would become overheated. But between a range of 35° F. on the one side and 75° F. on the other he is, in my opinion, safe in his closed oxygenated chamber. Whether he can descend to the same depths as other divers—say to 86 feet—and remain there, has to be proved. Theoretically, he ought to be able to do so, but in this field of inquiry he must

[1] Abstracted from lecture delivered to the Society of Arts on Thursday, May 8.

win his spurs. The lowest depth to which he has descended is 25 feet. He has walked under water a distance of four hundred yards in a straight line.

Some improvements may be made in the arrangements. He might be supplied with a feeding-apparatus, and so remain under water several hours longer than he has done. At present he finds from two to three hours no difficulty.

The experiments I have made with the apparatus indicate that the dress and apparatus may be used for entering wells, burning houses, and mines that are charged with suffocating gases. In the mine the dress would be invaluable, and if a telephonic connection could be set up between the man in the dress and the outside world—an adaptation I believe to be quite possible—a remarkably useful advance would be made.

I will now ask Mr. Fleuss to make one experiment which will be a visible exposition of the perfection of his apparatus as he stands equipped in it. The directors of the Royal Institution have been so good as to lend me the glass chamber in which Prof. Tyndall experimented when he was demonstrating the mask he invented for breathing in an atmosphere charged with dense fumes of smoke. This chamber I have had charged with carbonic acid, so that it has in it an irrespirable atmosphere. In it, as you will see, a candle cannot be lighted, and a taper will be extinguished. Mr. Fleuss will go into the chamber, sit down in it, and wait there until the current of carbonic acid which is being admitted forms an absolute atmosphere of the gas to above the level of the top of his helmet, and there he will remain, if we like, until the supply of oxygen in the helmet is exhausted.

The next step onward will be to construct a small closed canoe, in which the apparatus can be fitted on a larger scale, and in which men, or those who are in the canoe, can rise or sink in the water and be propelled under the water. This is a certain extension of the system now under our consideration, and when it is completed, my idea that the next greatest geographical discoveries will be made on the floors of the great oceans may not be so far wide of the mark as was once supposed.

B. W. RICHARDSON

THE AURORA BOREALIS[1]

OUR experiments on the electric discharge, which have been already published in the *Phil. Trans.* and the *Proceedings* of the Royal Society, enable us to state with some degree of probability the height of the aurora borealis when its display is of maximum brilliancy, and also the height at which this phenomenon could not occur on account of the great tenuity of the atmosphere.

In Part III. of our electric researches, *Phil. Trans.*, Part I. vol. 171, we have shown that the least resistance to the discharge in hydrogen is at a pressure of 0·642 millim., 845 M; after this degree of exhaustion has been reached a further reduction of pressure rapidly increases the resistance. When the exhaustion has reached 0·002 millim., 3 M, the discharge only just passes with a potential of 11,000 chloride of silver cells (11,330 volts); at the highest exhaust we have been able to obtain (and which we believe has not been surpassed), namely, 0·000055 millim., 0·066 M, not only did 11,000 cells fail to produce a discharge, but even a 1-inch spark from an induction-coil could not do so.

Although we have not experimentally determined the pressure of least resistance for air, we have ascertained that while the discharge occurs in hydrogen at atmospheric pressure between disks 0·22 inch distant, they require to be approached to 0·13 inch to allow the discharge to take place in air. We may therefore assume that the pressure of least resistance for air is

$$\frac{0{\cdot}642 \times 13}{22} = 0{\cdot}379 \text{ millim., } 498{\cdot}6 \text{ M.}$$

At a height of 37·67 miles above the sea level, the atmosphere would have this pressure (neglecting change of temperature), and therefore the display at this elevation would be of maximum brilliancy and would be visible at a distance of 585 miles.

The greatest exhaust that we have produced, 0·000055 millim., 0·066 M, corresponds to a height of 81·47 miles, and as 11,000 cells failed to produce a discharge in hydrogen at this low pressure, it may be assumed that at this height the discharge would be considerably less brilliant, especially in air, than that at 37·67 miles, the height of maximum brilliancy.

At a height of 124·15 miles the pressure would be only 0·00000001 millim., 0·00001 M, and it is scarcely probable that an electric discharge would occur with any potential conceivable at such a height.

The colour of the discharge varies greatly with the tenuity of air or other gas with the same potential. Thus in air at a pressure of 62 millim., 81579 M, the discharge has the carmine tint which is so frequently observed in the display of the aurora; this corresponds to an altitude 12·4 miles, and would be visible at a distance 336 miles. At a pressure of 1·5 millims., 1974 M, corresponding to a height of 30·86 miles, the discharge becomes salmon-coloured, having completely lost the carmine tint. At a pressure of 0·8 millim., corresponding to 33·96 miles, the tint of the discharge is of a paler salmon colour, and as the exhaust is carried further it becomes a pale milky white. The roseate and salmon-coloured tints are always in the vicinity of the positive source of the electric current, the positive luminosity fades away gradually, and frequently becomes almost invisible at some distance from its source; as, for instance, in the hydrogen discharge at a pressure of 2·3 millims., 3027 M, shown in the accompanying figure, H, which resembles in some

respects the phenomena of the aurora. The discharge at the negative terminal in air is always of a violet hue, and this tint in the aurora indicates a proximity to the negative source.

The following table, with the exception of pressure

[1] "On the Height of the Aurora Borealis." Paper read at the Royal Society. By Warren De La Rue, M.A., D.C.L., F.R.S., and Hugo W. Müller, Ph.D., F.R.S.

0·00000001 millim., exhibits deductions from actual observations:—

Pressure mm.	Pressure M.	Height miles.	Visible at miles.	Remarks.
0·00000001	0·00001	124·15	1061	No discharge could occur.
0·000055	0·066	81·47	860	Pale and faint.
0·379	499·0	37·67	585	Maximum brilliancy.
0·800	1053·0	33·96	555	Pale salmon.
1·000	1316·0	32·87	546	Salmon coloured.
1·500	1974·0	30·86	529	,, ,,
3·000	3947·0	27·42	499	Carmine.
20·660	27184·0	17·86	403	,,
62·000	81579·0	12·42	336	,,
118·700	156184·0	11·58	324	Full red.

It is conceivable that the aurora may occur at times at an altitude of a few thousand feet.

The following letter has been sent us in reference to the above paper:—

Meteorological Office, 116, *Victoria Street*, *London, S.W.*, *May* 1, 1880

With reference to a paper at the Royal Society on the height of auroras by Dr. De la Rue and Dr. Müller, the following remarks in Müller's "Lehrbuch der kosmischen Physik," 2nd Edition, 1865, p. 558, may be of interest to your readers:—

"Hansteen finds for the aurora of January 7, 1831, a height of 26 geographical miles, by combining the height of the arch at Berlin and Christiansand in Norway, while Christie calculates the height of the same aurora at between 5 and 25 English miles, from observations made in England.

"The determinations of modern physicists place the aurora at a much lower level than was formerly assumed. Mairan gave the mean height at 120, Cavendish (1790) at 60, and Dalton (1828) at only 18 geographical miles.

"Farquharson makes it probable that the auroras, as was already said by Baron v. Wrangell, come down to the region of the clouds. He bases this, *inter alia*, upon the auroral observations of December 20, 1829. At Alford, in Aberdeenshire, he saw, from 8.30 to 11 o'clock in the evening, a very brilliant aurora over a thick mass of clouds which covered the hills lying to the north of his house. Although the sky was clear the aurora never rose higher than 20°. At the same time the Rev. Mr. Paull, at Tullynessle, lying two English miles north of Alford, in a narrow side valley of the hills above mentioned, saw a very brilliant aurora close to the zenith about 9.15. This would give the height of the aurora as not more than 4,000 feet. This opinion is confirmed by numerous observations made in the Polar regions by Parry, Franklin, Hood, and Richardson. Franklin observed auroras between the clouds and the earth, which lit up the lower surface of thick clouds.

"So much is certain, the phenomenon appears in various heights, but can hardly be seen higher than twenty miles. The auroras formed at low heights, which are often seen in the Polar regions, are only visible at short distances. Hood quotes an aurora on April 2, 1820, at Cumberland House, as a brilliant arch of 10° altitude. Fifty-five English miles to the south-west nothing was visible.

"Another aurora on April 6, which remained in the zenith for some hours over Cumberland House, appeared at the distance of 100 English miles to the south-west as a steady arch only 9° in height."

The observation of Mr. Smith of Jordan Hill, at Loch Scavaig in Skye, of an aurora apparently emanating from a mountain there, will also be remembered.

ROBERT H. SCOTT

A SCOTTISH CRANNOG[1]

II.—*Objects of Bone*

Upwards of twenty implements made of bone have been added to the general collection, all of which were found either in the relic bed or refuse heap. The following are the most interesting.

1. Two chisels or spatulæ. One is made of a split portion of a shank bone, and measures 5¼ inches long

Fig. 6.—Bone (Scale ½.)

Fig. 7.—Bone (Scale ½).

and rather less than ½ inch broad. It is very hard, flat, and smoothly ground at one end, and has a sharp rounded edge, which extends farther on the left side, thus indicating that it was adapted for being used by the right hand. The other is a small leg bone obliquely cut so as to present a smooth polished surface. Its length is 4 inches, and its diameter ½ inch.

2. Five small objects presenting cut and polished surfaces, three of which are sharp and pointed; one

Fig. 8.—Horn (Scale ½).

Fig. 9.—Horn (Scale ½).

appears to have been notched at the end and there broken off; and the last, presenting well-cut facets, is fashioned into a neat little wedge.

3. Fig. 6 represents a tiny little spoon only ¾ inch in diameter, and worn into a hole in its centre. The handle portion is round and straight, and proportionately small,

[1] A full report of the Lochlee Crannog is given in vol. xiii. of the *Proceedings* of the Society of Antiquaries of Scotland, and in vol. ii. of the Collections of the Ayrshire and Wigtownshire Archæological Association. Continued from p. 16.

being only 2 inches long, and about the thickness of a crow-quill.

4. Fig. 7 is a drawing of a neatly-formed needle-like instrument. It is flat on both sides, finely polished, and tapering into points at its extremities.

5. Two curious implements smoothly polished and forked at one end. They are both about 5½ inches long, and precisely similar to each other in every respect.

6. A great many small ribs, about 6 or 7 inches in length, and portions of others, were found to have the marks of a sharp cutting instrument by which they were pointed and smoothed along their edges. The use of these implements can only be conjectured.

7. Lastly, there are several portions of round bones which appeared to have been used as handles for knives or such like instruments.

III.—*Objects of Horn*

About forty portions of horn, chiefly of the red-deer, bearing evidence of human workmanship were collected during the excavations. They consist of hammers or clubs, pointed tynes, spear-heads, &c. As illustrations of these implements, Figs. 8 and 9 are good representations of a club and a bodkin. The former is 11 inches long, and has about 3 inches of the brow branch of the horn projecting from it, round the root of which there is a groove, as if intended for a string. The markings on the back portion indicate very distinctly that it was used for hammering some hard substance; the latter is 8 inches long, finely polished all over, and pointed at the tip as if with a sharp knife.

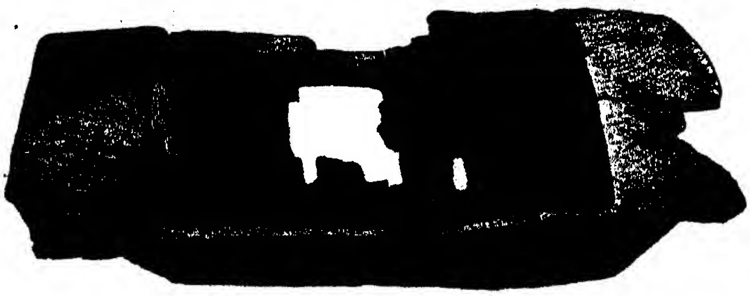

FIG. 10.—Wooden Vessel (Scale ⅛).

IV.—*Objects of Wood*

A large assortment of wooden implements was found, chiefly in the refuse heap, and in the portion of *débris* corresponding to the area of the log pavement. Owing to the softness of the wood and the large amount of moisture contained in its fibres, most of these relics have already shrunk to less than half their original bulk, and become so changed, though they were kept in a solution of alum for several weeks, that I am doubtful of being able to preserve them at all. They consist of bowls, plates, ladles, a mallet, a hoe, clubs, pins, &c., together with many objects entirely new to me, but which apparently had been used for culinary or agricultural purposes.

Fig. 10 represents a trough cut out of a single block of wood. It was found about half way between the margin of the crannog and the circle of stakes surrounding the log pavement at a depth of 5 feet, amongst decayed brushwood and chips of wood.

Canoes.—During the progress of the drainage a canoe, hollowed out of a single oak trunk, was found about 100 yards north of the crannog. Its depth in the moss was well ascertained, owing to the fact that, though lying at the bottom of one of the original drains, it presented no obstruction to the flow of water, and consequently was then undisturbed. During the recent drainage all the drains were made a foot deeper, and hence its discovery. It measures 10 feet long, 2 feet 6 inches broad (inside), and 1 foot 9 inches deep. The bottom is flat, 4 inches thick, and contains nine holes, arranged in two rows and about 15 inches apart, with the odd one at the prow. These holes are perfectly round and exactly 1 inch in diameter, and when the canoe was disinterred they were quite invisible, being all tightly plugged.

When the original drainage was made, some forty years ago, I understand that two canoes, each of which was about 12 feet long, were found in the bed of the lake on the south-west side of the crannog.

A double-bladed oak paddle, 4 feet 8 inches long and 5½ inches broad, and a large oar, together with the blade portion of another, were found amongst the *débris* on the crannog.

V.—*Objects of Metal*

(*a*) The chief articles made of iron are the following:—

1. A gouge, 8 inches long.

2. A chisel, 10 inches long. Both these tools had remains of bone or horn handles containing beautiful green crystals of vivianite.

3. Two knives. One has a blade 6 inches long, and a pointed portion for being inserted into a handle. It was found on a level with, and close to, the lowest hearth, along with fragments of its handle made of stag's horn. The other, found by a farmer in the *débris* long after it was thrown out of the trenches, was hafted on a different plan from the former, the end portion being broad, and riveted to its handle by four iron rivets, which still remain.

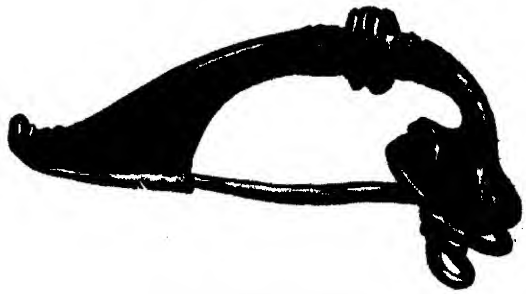

FIG. 11.—Fibula (Full size).

4. Two spear-heads, one prominently ridged, 13 and 9½ inches, with sockets for wooden handles, portions of which still remain in the sockets.

5. Five daggers. One has portion of a bone handle surrounded by a brass ferrule, and about an inch in front of this the corroded remains of a guard are seen.

6. A saw in three pieces, two of which were joined when found, and the third was lying a few feet apart. The length of the three portions together is 38 inches, and the average breadth is 3 inches.

7. A small corroded iron hatchet, with portion of a wooden handle in the socket.

8. A curious three-pronged implement was found, about 3 feet deep, in the large drain a few yards to the south of the crannog; the prongs are curved, very sharp at the points, and attached laterally; they are $2\frac{1}{2}$ inches apart, and 4 inches long.

(*b*) Of articles made of bronze or brass, the following may be noted:—

1. Two fibulæ—one of which is figured here (Fig. 11)—were found about the centre of the refuse heap, and a third, much more elaborately ornamented, was subsequently found in the *débris* when closing up the trenches.

2. A bronze ring pin, 6 inches long. The square-shaped portion of the top has a different device on each side, one of which is a *fylfot* (croix gammée or swastika), and the shank from its middle to the point is ornamented on both sides (Fig. 12).

3. A spatula or dagger-shaped inplement with blunt edges, measuring $11\frac{1}{4}$ inches long and $1\frac{1}{2}$ inch broad.

4. A thin spiral finger-ring.

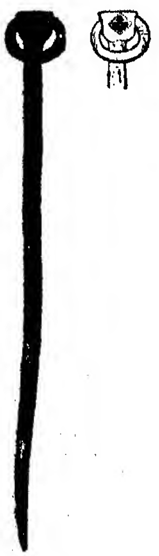

FIG. 12.—Bronze Ring Pin (Scale ½).

FIG. 13.—½ size. Made from stems of a moss (*Polytrichum commune*).

5. A bridle-bit. This consists of two large rings and a centre-piece. Its extreme length is $10\frac{1}{2}$ inches; the outer diameter of the rings is rather less than 3 inches, and the centre-piece, which is entirely made of iron, is $3\frac{3}{4}$ inches long. The rings are partly iron and partly bronze, the circular portion being iron, and the rest bronze. The bronze portion has two eyes or loops, one of which is attached to the centre-piece and the other free. This interesting relic was turned up by two visitors poking with a stick at the south-east corner of the refuse heap.

VI.—*Miscellaneous Objects*

1. *Carved Wood.*—Perhaps the most interesting of all the relics discovered on the crannog is a small piece of ash-wood, about 5 inches square, having curious diagrams carved on both sides. On one side three equidistant spiral grooves, with corresponding ridges between, start from near a common centre and radiate outwards till they join, at uniform distances, a common circle which surrounds the diagram. On the other side is a similar diagram, with this difference, that between the points of commencement of the spiral grooves there is a space left which is occupied by a small circular groove surrounding the central depression or point. This figure is surmounted and overlapped by two convoluted and symmetrical grooves meeting each other in an elevated arch, with a small depression in its centre. The relic was found on the west side of the crannog, about 4 feet deep, and near the line of the horizontal raised beams.

2. *Fringe-like Objects.*—Another object which has excited considerable curiosity is an apparatus made like a fringe by simply plaiting together at one end the long stems of a kind of moss. Portions of similar articles were found in three different parts of the crannog, and all deeply buried. The one figured here, and the most neatly formed, was found in the relic bed near the hearths (Fig. 13).

3. Among the remaining articles under this head are to be found some portions of leather, one thick bit being pierced by stout copper nails; a few glass beads and small rings made of bone; some fragments of pottery, one being the bottom of a jar, said to be Samian ware; portions of three armlets made of jet or lignite, together with one or two other fragments of objects made of the same material.

According to a report by Prof. Rolleston of Oxford, who kindly undertook the examination of the bones and horns collected on the crannog, the following animals have their skeletons represented:—The ox (*Bos longifrons*); the pig (*Sus scrofa*, variety, *domestica*), the sheep, old dun-faced breed (*Ovis aries*, variety *brachyura*); the red-deer (*Cervus elaphus*), very abundantly; the roe-deer (*Cervus capreolus*), scantily, though unambiguously; the horse (*Equus caballus*) is represented by only one shoulder-blade; and the reindeer (*Cervus tarandus*) by one or two fragmentary portions. Some of the bones and horns had their cavities filled with beautiful green crystals, which on analysis proved to be vivianite.

Among the specimens of wood used in the structure of the island Dr. Bayley Balfour has identified the following:—Birch, hazel, alder, willow, and oak. In addition to these some of the relics were found to be made of elm and ash.

ROBERT MUNRO

THE UNITED STATES WEATHER MAPS, AUGUST, 1878

THE most remarkable feature of the meteorology of the northern hemisphere for August, 1878, as compared with July preceding, was the enormous change which took place in the distribution of amospheric pressure over the Atlantic as far as lat. N. 60°, the change being greatest in the region around Ireland and the south-west of England, where it amounted to a fall of about the third of an inch. Pressure was also still further reduced over nearly the whole of the United States, particularly in the north, the deficiency from the normal at New York being 0·150 inch. In Europe this lowering of the pressure extended eastward into Russia as far as long. E. 40°, where it rose to nearly the average. It again fell on advancing further eastwards to 0·150 inch below the normal in the valley of the Irtish, rising however again to the normal over the western affluents of the Lena. Thus from the Rocky Mountains, across the United States, the Atlantic, Europe, and into Asia as far as the Lena, pressure was under the normal, in other words over a broad belt going half-way round the globe. This region of abnormally low pressure would appear to have stretched south-south-westward from Western Siberia, embracing the regions marked off by Syria, Egypt, Africa as far as Cape Colony, the Mauritius, Western India, and Turkistan. Also in Victoria, Tasmania, and New Zealand pressure was very low, being at Dunedin 0·372 inch less than the normal.

On the other hand, pressure was above the normal in the region of the Rocky Mountains, over South Greenland, Iceland, Farö, Shetland, and adjacent coasts of Norway;

about the normal over a limited patch of country lying to the north-west of the Caspian, and over the whole of Asia to the east of a line drawn through Ceylon, the Upper Ganges, and Lake Baikal, this latter area of high pressure extending as far south over Australia as Adelaide. Another area of high pressure spread from Central America eastwards across the West Indies, the north of South America, and the Atlantic to Africa.

In accordance with this distribution of pressure temperature was from one to two degrees above the normal in the United States, except in the north-east, where it fell to the average in the New England States, and fell still further to 1°·6 below it at St. John's, Newfoundland. Under the influence of the low pressure around Ireland the Weather Map shows a prevalence of strong breezes from the Atlantic over Western, Central, and Eastern Europe as far as Kiev, and over the whole of this wide region temperature was above the normal, most notably so over Great Britain and the south of Norway, the mean at Mandal being 4°·2 above the average.

Over England these Atlantic breezes were south-westerly, but in Scotland easterly. In England the month was one of the rainiest Augusts on record, and in the east of Scotland the rains were also unusually heavy. On the other hand, what invariably happens when the weather in the east of Scotland is characterised by rain and east winds, the weather of the West Highlands was dry and bright.

The comparatively insignificant region of higher pressure to the north-west of the Caspian, taken in connection with the markedly low pressure in Western and Central Siberia, exerted a striking influence on the weather of that region, since, owing to the northerly winds, which necessarily set in with stronger force than usual, temperatures fell to from two to three degrees below the normal from the Irtish to the Dnieper. On the other hand, over Northern Asia, to the east of long. 75°, temperatures above the average prevailed, the excess at Irkutsk being 3°·0. In Victoria, pressure being lower on the coast than in the interior, northerly winds set in, and under their influence the temperature of the colony rose generally to 1°·5 above the normal. In New Zealand pressure was not only very low, but diminished greatly from west to east over the islands, and owing to the strong westerly winds which accompanied this distribution of the pressure, the temperature fell generally 2°·5 below the average of this winter month.

THE IRON AND STEEL INSTITUTE

FOLLOWING close upon the Institution of Mechanical Engineers came the meeting of the Iron and Steel Institute. The bill of fare of the younger association was certainly longer, and will probably be found not less interesting, than that of its elder colleague. It contained eleven papers on subjects of practical importance connected with the nature and manufacture of iron and steel. All of these papers were valuable, five of them especially so, and they prove beyond a doubt that the Iron and Steel Institute is doing immense service to metallurgical science in collecting and systematising practical information, and in affording opportunities for the discussion of theoretical opinions.

It was naturally to be expected that the recent meeting would furnish some information as to the practical working and commercial success of the Thomas-Gilchrist process of producing Bessemer steel from inferior brands of pig-iron, and especially from those descriptions, like Cleveland pig, which are rich in the very deleterious ingredient, phosphorus. At the last spring meeting of the Institute this process was little more than an idea, but it was clearly seen that if it could be rendered a commercial success its influence on the future of the North-Eastern iron district of this country could not fail to be enormous. Accordingly we are not surprised to find two papers on this subject, one by Messrs. Holland and Cooper, of Sheffield, entitled "On the Manufacture of Bessemer Steel and Ingot Iron from Phosphoric Pig," and the other by Mr. R. Pink, of the Hœrde Works, Westphalia, "On the Dephosphorisation of Iron in the Bessemer Converter." From these two papers we learn the most recent results of British and German experience, and it must be deemed a matter of great congratulation that in both countries much good progress seems to have been made in the practical working of the new process.

The difficulties encountered were only such as are always encountered in the introduction of any new method. The first of these minor troubles experienced in Sheffield was to find out the right moment when to stop blowing. "It seemed doubtful whether it would be practicable (having no definite point at which we could safely stop blowing, corresponding to the drop of the carbon flame in the ordinary process) to burn out the whole of the phosphorus regularly, without sometimes carrying the process too far, and thereby oxygenating the charge. And this, as all steel makers will agree, is very apt to give trouble." However, by taking samples of the metal from the converter during the "after-blow," and testing them, it was found practicable to stop the process at the right time, and to remove the phosphorus in a very satisfactory manner. Here, however, a new difficulty arose. The time lost while the samples were being taken enable the slag and metal to accumulate at the "nose" of the converter, and partially choke the aperture, thus causing great inconvenience and loss of time in removing the obstruction. By reducing the area of the aperture, and thus retaining the heat better in the converter, and by lining the nose with fire-brick, this difficulty was partially got over, but the accumulations of slag still continued at the junction of the fire-brick and bassic lining of the converter. Increased experience, however, soon enabled the Sheffield manufacturers to complete the blowing by timing with a watch, without the testing of samples, and as no time was given for the accumulation of slag, no further trouble was experienced. How completely the timing system answered may be judged from the following extract from Messrs. Holland and Cooper's paper:—"In the week ending April 17, when not a single sample was taken during the operation, except in the case of the experimental blow 748, the average amount of phosphorus contained in 36 blows, all of which were analysed, was ·056 per cent., the highest being ·101 per cent., and the lowest ·019 per cent." The composition of this quality of steel has been in other respects very regular, the analyses and results of a test piece 2 inches long and ·533 inches in diameter being as follows:—

Carbon.	Silicon.	Sulphur.	Phosphorus.	Manganese.	Breaking strain, tons.	Elongation per cent.	Reduction of area per cent.
·40 ...	— ...	·040 ...	·085 ...	·662 ...	39·75 ...	20·25 ...	31·84

It has been found that since sampling has been dispensed with, that the wear of the lining of the converter is very uniform. As many as 630 tons of steel have been produced from one lining, without any repairs excepting a new fire-clay brick-lining for the nose; and 270 tons more were got from the same lining after renewing the front or blowing side, and putting in a new nose. This absence of difficulty about the renewal of the plant, coupled with the excellent quality of the metal produced, show that the process must now be pronounced a commercial success.

The experiences of the Sheffield manufacturers were amply borne out by the results arrived at at Hœrde. Mr. Pink says in the beginning of his paper: "Without doubt we are on the verge of making from the *very worst classes of pig iron a most reliable and remarkably cheap steel*," and this assertion is amply borne out by the results of chemical analysis and mechanical testing which he

publishes. "In the softer qualities for plates, wire, &c., it is at times astonishing what results are obtained. With 37 to 40 kilogrammes of actual breaking weight, as much as 70 per cent., and in some cases even 75 per cent. of contraction has been reached. At the same time this ingot iron can take very high heats, forging and rolling without a flaw. The production of this especial quality is so simple, the cheapness of the raw material, the certainty in working, its softness, and its ductility, all point to its driving at no very distant date puddled iron plates out of the market. For wire even of the smallest gauges it has been declared better than that drawn from billets puddled from charcoal pig."

This is an extremely good result to have attained in the short space of less than a year, and gives good ground for the hope of further improvement in the future. The manufacturers do not appear as yet to have quite succeeded in producing a hard steel by this process.

The remainder of Mr. Pink's paper contains an account of very similar difficulties experienced and overcome to those described by Messrs. Holland and Cooper.

A paper of considerable practical interest was read by Mr. Henry Simon, C.E., of Manchester, "On an improved System for the Utilisation of Bye-Products in the Manufacture of Coke." It is well known that in the manufacture of gas for lighting purposes the sale of the bye-products, such as tar and ammoniacal liquor, which are obtained during the distillation of the coal, is one of the chief sources of profit. In the manufacture of coke it has hitherto been the practice in this country to allow the tar and ammoniacal liquor to run to waste. Such a course not only causes waste, but increases the great nuisance of coke ovens to the neighbourhood in which they are planted. The extent of the waste may be inferred when it is stated that at Manchester the gas-works obtain 38*s.* per ton for tar, and from 20*s.* to 25*s.* per ton for their ammoniacal liquor; and it has been found at Bessèges, in France, where the bye-products are saved, that every ton of coke obtained gives nearly 3 cwts. of ammoniacal liquor, and 72½ lbs. of tar, worth together, at Manchester prices, about 4*s.* 6*d.* per ton of coke produced.

In this country over 7,000,000 tons of coke a year are produced for the manufacture of pig-iron alone, the value of the bye-products of which is about 1,350,000*l.*, a sum which is annually lost to the nation. The demand for the ammoniacal liquor, both for agricultural purposes and for the manufacture of soda, is practically unlimited. As an instance of the truth of this statement it may be mentioned that one firm of soda-manufacturers, viz., Messrs. Solway, have contracted for the whole production of the Bessèges Works, and transport it 300 miles by rail to their factory near Nancy.

By the new method of production nearly the whole of the noxious effect of the old "beehive" coking ovens is done away with. So great are these ill-effects that in the words of the Royal Commission on noxious vapours, which sat in 1877, "all vegetation near coke ovens, conducted on the older methods, suffers severely. The growth of trees is checked or destroyed, fences are killed, crops of every description are injured, cattle suffer, and upon many occasions the effect of the vapours emitted by coke ovens is terrible." In the counties of Durham and Northumberland alone 6,000,000 tons of coal are annually coked, and in the process give off 2,000,000 tons of vapours, which consist in great part of the valuable tars and nitrogenous compounds which might so easily be saved. The quantity of sulphurous acids which escape into the atmosphere every year in these districts is estimated to be about 70,000 tons.

In the process described by Mr. Simon "the coal is rapidly carbonised by subjecting a comparatively thin layer of it to a high temperature in a closed and retort-like vessel, and whilst in the beehive ovens the volatile products are burned inside, we burn them around the outside of this retort-like vessel, and only after they are deprived of the tar and ammoniacal liquor." Besides saving these products, the heat of the hot gases is utilised greatly for the production of steam. At Bessèges about 45 pounds of water is evaporated into steam of 4½ atmospheres pressure per hour and per ton of coal coked; and it is said that under more favourable circumstances 59 pounds might be evaporated. The remainder of the paper contains a technical description of the new apparatus, the advantages of which are stated to be as follows:—

"1. Greater yield of coke by about 10 per cent.

"2. Greater purity of coke.

"3. A yield of about 4*s.* worth of useful bye-products per ton of coke.

"4. An almost entire absence of smoke or noxious vapours.

"5. In comparison with any other existing system of coke ovens, equal facilities for utilising the heat, and a reduced cost for repairs."

Messrs. John Parry and Alexander Tucker read a joint paper "On the Application of the Spectroscope to the Analysis of Iron and Steel." They commenced by noticing that the analysis of iron and steel is usually summed up in percentages of iron, manganese, carbon, silicon, sulphur, and phosphorus, and perhaps copper, nickel, and cobalt, and suggested that other elements might also be at work, and that we ought not to remain satisfied with percentages of the above substances till we have proved the absence of others. It has, however, been found extremely difficult to prove the absence of the rarer elements, partly because the traces of these latter are apt to accompany the large mass of iron throughout the chemical processes. Under these circumstances it was thought that the spectroscope, which has done so much good work in other departments of chemistry, might be usefully employed.

"Theoretically a well-focussed photographed spectrum of a steel should be an unerring index to its composition; this is partly true in practice, but it is not in our experience absolutely so." "We have found the spectra of pure iron, Bessemer steel, tool steel, chrome steel, Siemens' steel, and pig iron to be decidedly different, and the differences would be characteristic, but they failed to show the presence of bodies which further experiment proved to exist." "There are several reasons why this should be the case.

"1. The number of lines due to iron is so great (100-130) that they overlap in the small spectra the lines due to other bodies, and our apparatus does not readily allow of images larger than one or two inches being taken.

"2. The intensity of light due to the traces of bodies may not be sufficient to record lines on the plate.

"3. Because of the variation in the volatility of the elements, and therefore the necessity of variation in the intensity of the spark."

The authors therefore thought it important either to separate the iron or considerably lower its percentage, and the solution of this problem was their principal aim. The results of their experiments have led them to believe that as a rule the quantity of iron is much over-estimated. In confirmation of this opinion they also quote the fact that iron and steel are capable of absorbing twenty times their volume of hydrogen, a quantity which is always omitted in ordinary analysis, "which is probably due to the fact that a steel saturated with hydrogen must be less liable to oxidation in the heating furnace than one containing little or none. In order to eliminate the iron a method of digestion with various solvents was adopted. By this process much larger quantities can be operated on at a time than by the ordinary methods of precipitation. As much as 7,000 grains of Bessemer steel were dissolved in *aqua regia*. The solution was evaporated and heated in a paraffin bath till the acids were driven off. Ammonia

was then poured on and allowed to act under pressure for several hours. It was then filtered off and evaporated to dryness with nitric acid, so as to decompose any ammonia salts. The residue was then treated in three different ways, and the spectrum photographed in each case.

1. With excess of hydrochloric acid. 2. Water was added to the iron and boiled with it. 3. Acetic acid was added and boiled with the iron, some of which was dissolved, and the solution was therefore nearly neutralised with ammonia and boiled. Photographs were then taken of the spectra of the iron thus precipitated and the filtrate from it. The following is a summary of the results obtained :—

Ammonia.	Water.	Acetic Acid.
Nickel	Calcium	Antimony
Cadmium	Manganese	Lead
Calcium	Copper	Aluminium
Manganese		Copper
Copper		Calcium
		Manganese

"The above experiments were made with 7° coils and dense prisms of 60° and 75°, with object-glasses of quartz. By using an electro-dynamic machine a greater dispersion might be used, and the length of the image increased. We think that it would then be found that the bodies which we have detected by indirect means would appear in the spectrum of the original metal."

In addition to the above Mr. Wrightson read a second paper "On some physical changes occurring in Iron and Steel at High Temperatures," which was a continuation of a paper read by him at the Liverpool meeting last year. Mr. Ackerman, of Stockholm, contributed a very lengthy memoir "On Hardening Iron and Steel; its Causes and Effects." There were also five other papers on subjects of importance, chiefly to those technically interested in the manufacture of iron and steel.

In conclusion the Institute must be congratulated not only on the importance and number of the papers produced, but also on the fact that it has succeeded in obtaining contributions from three foreign countries, viz., Germany, Russia, and Norway, a circumstance which will no doubt give to the proceedings of the association an international importance.

NOTES

Mr. W. Chandler Roberts, F.R.S., Chemist of the Mint, has been appointed to the Lectureship of Metallurgy in the Royal School of Mines, rendered vacant by the resignation of Dr. Percy, F.R.S. Mr. Roberts will continue to hold his appointment at the Mint. Mr. Richard Smith, hitherto Assistant Metallurgist, has been appointed Instructor in Assaying.

The following foreign men of science have recently (May 6) been elected Foreign Members of the Linnean Society :—M. C. J. de Maximowicz, Director of the Imperial Museum and Herbarium, St. Petersburg, author of many important memoirs on systematic botany; Dr. Edward Strasburger, Professor of Botany in the University of Jena, well known for his morphological and physiological researches among various groups of plants; and Prof. Elias Metschnikoff, Director of the Embryological and Zoological Institute, Odessa, whose investigations on the structure and development of the lower marine invertebrata are highly valued.

The Municipality of Rome has just erected on the promenade of the Pincio a statue in honour of Father Secchi. The statue represents the great astronomer in the attire of a member of the Company of Jesus.

Under their present government the French are multiplying the statues erected to their men of science by means of public subscription. Not less than three new schemes are on foot for that purpose in several parts of the country. A committee has been established at Montpellier for Auguste Comte; another at Blois, in honour of Denis Papin, a rival of the Marquis of Worcester, who, according to the French notion, invented the steam-engine; and a third at Bar-le-Duc, on behalf of François Cugnot, an engineer born in the vicinity of that city, who in 1770 constructed a road-locomotive. This rudimentary steam-engine, which is exhibited just now at the Conservatoire des Arts et Métiers, was tried officially but unsuccessfully in the arsenal of Paris more than a century ago.

Dr. Nils Johann Andersson, the celebrated Swedish botanist and traveller, as the *Gardener's Chronicle* learns from the *Botanisches Centralblatt*, died after long suffering on March 27 at Stockholm. Andersson was born on February 20, 1821, studied at Upsal, graduated as Doctor of Philosophy in 1845, and resided at the University as Assistant Professor of Botany. Afterwards he took part in the expedition of the frigate *Eugénie* round the world, 1851-1853, the result of which he published in several treatises which were translated into various foreign languages. In 1855 he became Demonstrator of Botany at Lund, and in the following year was appointed permanent Professor of Botany, Director of the Bergianska 'schen Garten and Superintendent of the botanical division of the Royal Museum. There he worked with great success till the beginning of 1879. From here Andersson undertook numerous journeys in the cause of science to Lapland, Norway, Germany, France, England, &c. He also acquired scientific renown through his various treatises, books of travel, and text-books.

Prof. Silvestri, of Catania, reports as follows concerning the renewed activity of Etna, to which we referred last week :— "The eruption issues from the western side of the mountain, precisely the part which separates the central crater from the eruptive craters of last year. The situation indicated represents the principal part of the ravine which was then formed and remained opened, and which, beginning at the recent eruptive craters, finally crosses the great crater. This ravine, in which are many crater-caverns which opened last May but remained inactive, is now the scene of the present activity, limited as yet to a simple eruption of steam and ashes, such as has frequently taken place during the past months at the summit of the mountain. To-day (April 28), while the sky is cloudless, one sees from Catania the summit of Etna enveloped in clouds which, scattered by a rather strong north-east wind, have no resemblance to eruptive clouds, though they are formed by the steam issuing from the mountain. The eruption of mud at Paterno to the south still continues, and on certain days in some of the craters increases in energy, ejecting as abundant mud as during the first days after the appearance of the phenomena."

On Tuesday evening a paper on the botanical enterprise of the empire was read to the Colonial Institute in St. James's Hall by Mr. Thiselton Dyer, assistant director of Kew Gardens. The lecturer gave a history of botanical gardens, which date from the middle of the sixteenth century, when Alfonso d'Este, Duke of Ferrara, the patron of Tasso, set the fashion of making collections of foreign plants and flowers. The earliest public botanic garden was founded by Cosmo de' Medici in 1544 for the University of Pisa. The following year one was founded at Padua. In France the earliest botanic garden was founded at Montpellier towards the end of the sixteenth century, and in Germany that of Giessen was established in 1614, and in the Low Countries that of Leyden dated from 1577. In England the Royal Garden at Hampton Court was founded by Queen Elizabeth, and supported by Charles II. and George III. Those which followed and still remain were Oxford, founded in 1632; Chelsea, in 1673; and Edinburgh, in 1680. The origin of Kew as a

scientific institution was entirely due to our Hanoverian princes. During the reigns of George IV. and William IV. Kew was much neglected; but since that date, owing to the efforts of Lindley and Sir W. Hooker, that state of things had been remedied. The lecturer gave a long and elaborate account of the methods pursued and the objects aimed at in the gardens at Kew. There was hardly any country of which a native would not recognise some types of vegetation with which he had been familiar. Plant distribution to all parts of the world was extensively carried out from the gardens, especially that of cinchona, caoutchouc, and Liberian coffee. The herbarium, which was the largest and best organised in the world, and the library, were important features in the gardens, and served to promote a scientific method of nomenclature, identification, and classification. In 1863 the Duke of Newcastle, then Colonial Secretary, instructed Sir W. Hooker to publish a series of colonial floras; and twenty-two volumes had been issued and others were in progress. The floras of Australia and British India were especially valuable. In the former there were 293 species of acacia and 135 of the eucalyptus. Floras had also been published of Hongkong, Mauritius, and the Seychelles, the British West Indies, and New Zealand. The example of Kew in the matter of museums and economic botany had been followed by Hamburg, Berlin, Ghent, Paris, Boston, and our own colonies. The whole vegetable collections of the India Museum had been recently transferred to Kew. One of the most striking features of the gardens was the enormous correspondence with the botanic establishments of the colonies. Mr. Dyer then indicated the principles which should guide the establishment of a colonial botanic garden; one of the chief of these was that it should be attractive and conveniently situate. It was also most important that it should be under competent management, and he was glad to see that the emoluments of directors had in some of our colonies been fixed on a liberal scale. Mr. Dyer concluded by reviewing the progress made by our colonies in botanical research.

In the first four months of 1880 the receipts for telegrams in France have been increased by 1,500,000 francs, but the postal department lost one-sixth of that amount. This result shows that owing to the low rate of telegrams in France (½*d.* per word) and the increased postage (1½*d.* per letter), telegraphy is gradually taking the place of ordinary letters.

Mr. S. H. Wintle contributes to the *Launceston Examiner* (Tasmania) of Feb. 20 some curious facts with regard to a "black snake" which he succeeded in capturing by pinning to the ground with a forked stick. In his haste Mr. Wintle pinned the snake to the ground by the middle of the body; what then occurred we give in his own words without comment:—"No sooner had I done so—for now his rage was at its highest pitch—than in an instant he buried his fangs in himself, making the spot wet either with viscid slime or the deadly poison. Now comes that which is of most interest from a scientific point of view. He had hardly unburied his fangs when his coils round the stick suddenly relaxed. A perceptible quiver ran through his body, and in much less time than it takes to write it he lay extended and almost motionless, with his mouth opening and shutting as if he were gasping, but no forked tongue thrust out. In less than three minutes from the time he bit himself he was perfectly dead. Here, then, was a striking example of the potency of the fang-poison of the snake upon itself." An hour after the death of the snake Mr. Wintle tried the effect of the poison in the fangs on a mouse, which died in five minutes, and on a lizard, which died in fourteen minutes. On a *post-mortem* examination of the snake the body was found almost bloodless, "as though the action of the poison had destroyed the colouring-matter of the blood."

Mr. F. Lewis, jun., of Ballangoda, Ceylon, sends us a snake story in connection with the correspondence on intellect in brutes:—"A short time ago," he says, "I caught a common 'green snake,' and, anxious to try its power of intellect, I brought my finger close to its nose, and seeing that it seemed disposed to bite, I introduced the end of a match close to its mouth. This it did not seem to care about touching, so, thinking perhaps that if I moved it about before the animal's eyes it might attract its attention, I did so, but without success. I then took the animal by the neck, and brought *its own tail* before its nose. This it grasped at immediately, and with considerable ardour, but still refused the match! Why should the snake prefer its own tail upon which to exercise its temper? I would suggest that if a few experiments were tried on animal instinct or intelligence some remarkable facts might be elicited, and probably some light thrown upon a subject at present so intricate and complex."

On Tuesday next (May 18) at the Royal Institution Mr. J. Fiske will give the first of a course of three lectures on American Political Ideas viewed from the Standpoint of Universal History; on Thursday (May 20) Mr. T. W. Rhys Davids will give the first of a course of three lectures on the Sacred Books of the Early Buddhists. The following are the arrangements for the remaining Friday evenings: May 21, Mr. W. Spottiswoode, on Electricity *in transitu*; May 28, Mr. Francis Hueffer, on Musical Criticism; and June 4, Mr. H. H. Statham, an Analysis of Ornament.

M. W. de Fonvielle has discovered a very simple process for putting in rotation his newly invented electro-magnetic gyroscope. It is sufficient to connect one end of the frame with each part of the self-acting interrupter. The only difficulty is to place the magnets at a proper distance and not to use a stronger voltaic current than required. For this operation to succeed, it is desirable to understand well the manœuvres of an instrument constructed on purpose. Some of the so-called electro-medical bobbins succeed remarkably well, either with the primary, the secondary, or a combination of the two working in tension.

A part of the St. Gothard Tunnel, 6,300 metres from the south entrance, has fallen in, killing three workmen and injuring three others.

Five walled tombs, each containing a skeleton, have been discovered at Chamblandes, Canton Vaud. From the absence of metal ornaments and other indications, they are supposed to belong to an age prior to that of bronze.

On May 9 a large number of officials and others assembled at Noailles to celebrate the completion of a rural railway with narrow gauge, of which we mentioned the inauguration a few months ago. The speculation is succeeding very well, and great improvements have been realised in all the surrounding country since the system has been in operation.

The additions to the Zoological Society's Gardens during the past week include a Silver-backed Fox (*Canis chama*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Tayra (*Galictis barbara*) from South America, presented by Mr. G. A. Muhlhaüser; an Indian Chevrotain (*Tragulus meminna*) from Ceylon, presented by Mr. W. H. Ravenscroft; a Ruddy Ichneumon (*Herpestes smithi*) from India, presented by Mr. A. R. Lewis; two Slow-worms (*Anguis fragilis*), British, presented by Mr. O. Thomas; five Bosca's Mud Newts (*Pelonectes boscai*) from North Spain, presented by Dr. A. Günther, F.Z.S.; an Indian Cobra (*Naia haje*) from India, presented by Mr. W. R. Higham; a Macaque Monkey (*Macacus cynomolgus*) from India, a Goffin's Cockatoo (*Cacatua goffini*) from Queensland, deposited; four Upland Geese (*Bernicla magellanica*) from Patagonia, purchased; an Axis Deer (*Cervus axis*), a Zebu (*Bos indicus*), born in the Gardens.

GEOGRAPHICAL NOTES

It is a great relief to learn that a letter has been received at St. Petersburg through Pekin from Col. Prejevalsky, dated from the town of Si-Ning, March 20, announcing that the expedition under his command is safe. He left the Nan Shian mountains in July, and entered Thibet through Shaidash. His party were attacked by Tangnts, of whom they killed four and put the remainder to flight. The Thibetian troops stopped the progress of the expedition 250 versts from Hlassa, and a messenger from the Grand Lama of Thibet brought the refusal of the Thibetian authorities to allow the Russians to proceed. The latter were, therefore, obliged to return, which they did with some difficulty through Northern Thibet, wintering at a height of 16,000 feet above the level of the sea. Col. Prejevalsky expects to reach Kiakhta in August by way of Alashan Urgu.

At the meeting of the Geographical Society on Monday last, Mr. Everard F. im Thurn, late of the Georgetown Museum, read a paper nominally descriptive of one of his journeys into the interior of British Guiana, but which also furnished much interesting information about that country generally. Mr. im Thurn first gave an account of the four tracts, parallel to the sea-coast, into which British Guiana may be divided, and afterwards of his journey up the Essequibo to the Savannah tract, over which he passed into Brazilian territory. At the Warraputa Cataracts he saw for the first time the rock-pictures which form so strange an addition to the landscape in parts not only of South, but of North America. The figures represent men, monkeys, snakes, &c., and are on a small scale. These pictures in Guiana are not of one kind, some being cut deeply into the rock, while others are merely scratched on the surface. Mr. im Thurn speaks well of the climate of British Guiana away from the coast, the chief drawbacks in the interior being fever, not of a dangerous kind, diarrhœa, and ophthalmia, the germs of the last being probably conveyed by the countless small flies with which the country is infested. His allusions to the flora of the region were particularly interesting, and from a remark which he made we are glad to believe that we shall have a book from his pen before long on this little understood colony. Mr. Flint, who had been Mr. im Thurn's companion, afterwards gave a brief description of an expedition he had made to the Roraima Mountain on the western frontier of British Guiana. He does not believe in the reported inaccessibility of this wonderful mountain, and roundly asserted that no serious attempt had yet been made to ascend it, previous travellers not having approached within a considerable distance of its base.

Mr. Douglas W. Freshfield, writing to the *Times*, states that further letters have been received from Mr. E. Whymper, announcing his ascent of Pichincha and his meeting with M. Wiener, who is about to explore the Napo country. Fuller and more formal accounts of Mr. Whymper's exploits have been received, but by his request they will not be made public until after his return in June.

In continuation of our note (Nature, vol. xxi. p. 526) on Mr. Easton's journey in the extreme north-west of China, we learn from a further instalment of his diary some additional particulars respecting his travels. After leaving Shunhwa-ting on the upper waters of the Yellow River, he intersected at right angles the longitudinal range of mountains that runs along the north bank, and after a hard climb of fifteen miles he reached Ba-rung, a small mud-walled town under the jurisdiction of Sining. The hills are of mud, and landslips have split them in all directions; they are uncultivated, and scarcely a blade of grass is to be seen. An extensive view was obtained from the top, and far away on the western horizon were seen snow-capped peaks of high mountains. Sining-fu, where Col. Prejevalsky is believed to have fixed his head-quarters for the present, was afterwards visited, and this city is described as "rather large and oblong, but really a very shabby place;" it is stated to be 400 miles distant from Tsinchow-fu, the head-quarters of the China Inland Mission in the interior of the Kansu province. On his return to that place from Sining, Mr. Easton crossed the Yellow River near Sincheng, about 100 miles from Sining, and he describes its width at that point as about 100 yards, but further down it widens to about 150 yards. The river winds very much, and abounds in rapids.

Where at one time, says the Eureka *Leader*, was Ruby Lake, there is at present not a drop of water. This sheet of water, seven or eight years ago, was from eighteen to twenty miles in length, and varied in breadth from half a mile to two or three miles, and was in a number of places very deep. It was fed by numberless springs along the foot of Ruby Mountain, and was the largest body of water in Eastern Nevada. For a number of years past it has been gradually drying up, until at last it has entirely disappeared. What has been the cause of this is a mystery. The Ruby range of mountains is considered the largest and finest between the Rockies and the Sierra Nevadas, and besides being well wooded, has been the best-watered range of mountains in Nevada.

A party of United States engineers has recently taken soundings of the Niagara River below the falls. It was a work of great difficulty to approach the falls in a small boat. Great jets of water were thrown out from the falls far into the stream, and the roar was so terrible that no other sound could be heard. The leadsman cast the line, which gave 83 feet. This was near the shore. Further down stream a second cast of the lead told off 100 feet, deepening to 192 feet at the inclined railway. The average depth of the Swift Drift, where the river suddenly becomes narrow with a velocity too great to be measured, was 153 feet. Immediately under the lower bridge the whirlpool rapids set in. Here the depth was computed to be 210 feet.

The German African Society, in the last number of its *Mittheilungen*, publishes a list of all the scientific expeditions sent out by the (former) German Society for the Investigation of Equatorial Africa, and by the new Society (under its present title) during the years from 1873 to 1879. Altogether there were no less than eight expeditions, viz.:—1. The Loango-Expedition, and to the Chinchoxo Station, 1873 1876; cost 10,532*l.*, less 1,133*l.* realised from sale of specimens; leader, Dr. Paul Güssfeldt, not Prof. A. Bastian (who took part at his own expense in the preparatory steps for the establishment of the Chinchoxo Station). 2. The Ogowe-Expedition of Dr. Oscar Lenz, 1874-1876, cost 1,563*l.* 3. Cassange-Expedition, 1874-1876, cost 4,457*l.* Members: Capt. A. von Homeyer, Dr. Paul Pogge, Herm. Soyaux, Lieut. A. Lux. 4. Eduard Mohr's Expedition, 1876, cost 692*l.* 5. Engineer Schütt's Expedition, 1877-1879, cost 2,590*l.* 6. Dr. Max Buchner's Expedition, since 1878, cost (till October, 1879) 1,523*l.* 7. Rohlfs' Expedition, since 1878, cost (till October, 1879) 2,255*l.* Members: Dr. Gerhard Rohlfs, Dr. Anton Stecker. 8. Dr. Oscar Lenz's Expedition to Marocco, since the end of 1879.

In his just published report on Borneo H.M.'s Consul-General says that owing to its geological formation the soil of the island cannot be compared with that of Java, Sumatra, the Sulu Archipelago, and the Philippines, all islands of volcanic origin. Towards the north, however, and in the plains in the neighbourhood of the Great Kina Balu range, the soil is exceedingly good, as is shown by the success with which the natives grow in their rude manner rice, tapioca, indigo, &c. At present the greater part of the island is clothed with a dense primæval forest of lofty trees, many of which afford excellent timber, and until the virgin soil thus covered has been cleared it is useless to speculate on the mineral resources of the country, but there is no doubt of the existence of coal, antimony, ore, and gold in Northern Borneo. Mr. Treacher, we may add, accompanies his report with a useful sketch-map of this part of the island.

Dr. Dutrieux, who until quite lately was on the staff of the first Belgian expedition to East Central Africa, has just published at Brussels (Lebègue et Cie.) some of the results of his observations in that country, under the title of "La Question Africaine au point de vue Commerciale."

In a communication, entitled "Cimbébasie," in the last number of *Les Missions Catholiques*, Père Duparquet furnishes a good deal of interesting information respecting Ovampo-land in Western Africa. Père Duparquet gives, in fact, a rapid sketch of his explorations from Olokonda to Quanhama in about 17° S. lat., 16° E. long. He has besides, however, collected a mass of notes about a large tract of country hitherto almost entirely unknown, and of which he expresses a high opinion.

The new number of *Les Annales de l'Extrême Orient* is chiefly occupied with an instalment of Prof. P. J. Veth's notes on the languages and literature of Java, and the interminable question of M. J. Dupuis and Tongking.

In the new number of the *Verhandlungen* of the Berlin Geographical Society (Band vii. No. 3) Herr Flegel gives an exceedingly interesting account of his residence in West Africa,

his visit to the Cameroon Mountains, and his ascent of the river Binué.

THE *Bolletino* of the Italian Geographical Society for April contains full details of the proposed Arctic Expedition under Lieut. Bove, with a carefully compiled map of the south polar regions so far as these have been hitherto explored.

M. DESIRÉ CHARNAY has left New York for Mexico for the purpose of carrying out a thorough exploration of the ancient remains that still exist in that country. It is expected that the work of exploration will last for two or three years.

ON ELECTRIC LIGHTING[1]

DYNAMO-ELECTRIC MACHINES.—Since the date of the author's former paper in April, 1879, other observers have published the results of experiments similar to those described by him. It may be well to exhibit some of these results reduced to the form he has adopted, viz., a curve, such as that shown in Fig. 4, *Proceedings*, 1879, Plate 29, and now reproduced, with slight alterations, in Fig. 1. Here any abscissa represents a current passing through the dynamo-electric machine,

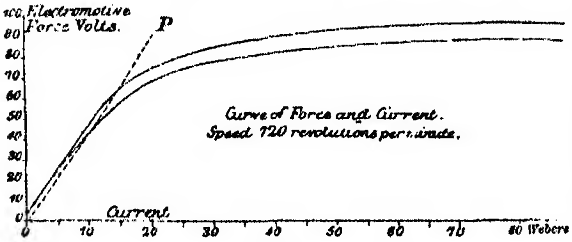

FIG. 1.

and the corresponding ordinate represents the electromotive force of the machine for a certain speed of revolution, when that current is passing through it. It will be found (1) that with varying speed the ordinate or electromotive force, corresponding to any abscissa or current, is proportional to the speed; (2) that the electromotive force does not increase indefinitely with increasing current, but that the curve approaches an asymptote; (3) that the earlier part of the curve is, roughly speaking, a straight line, until the current attains a certain value, and that at that point the electromotive force has reached about two-thirds of its maximum value. When the current is such that the electromotive force is not more than two-thirds of its maximum, a very small change in the resistance with speed of engine constant, or in the speed of the engine with resistance constant, causes a great change in the current. For this reason such a current, which is the same for all speeds of revolution, since the curves for different speeds differ only in the scale of ordinates, may be called the "critical current" of the machine. The effect of a change of speed is exhibited in Fig. 1, where the lower line represents a curve for a speed of 660 revolutions per minute, instead of 720. The resistance, varying as $\frac{\text{electromotive force}}{\text{current}}$, is given by the slope of the line O P, which must therefore be constant; and it will be seen that this line cuts the upper curve at a point corresponding to a current of 15 webers, and the lower at a point corresponding to a current of 5 webers only.

In Germany, Auerbach and Meyer (*Wiedemann's Annalen*, November, 1879) have experimented fully on a Gramme machine at various speeds, and with various external resistances. The resistance of the machine was 0·97 ohms. Their results are summarised in a table at the end of their paper, which gives the current passing, with resistances in circuit from 1·75 to 200 Siemens units, and at speeds from 20 to 800 revolutions per minute. In the accompanying diagram, Fig. 2, curve No. 1, expresses the relation between electromotive force and current, as deduced from some of their observations, making allowance, where necessary, for difference in speed. The curve, as actually constructed, is for a speed of 800 revolutions: at this speed it will be seen that the maximum electromotive force is about 76 volts; the critical current, corresponding to a force of about 51 volts, is 6·5 webers, with a total resistance of 7·8 ohms. Up to this point there will be great instability, exactly as was the case in the Siemens machine examined by the author, where the resistance was 4 ohms, and the speed 720 revolutions.

The results of an elaborate series of experiments on certain dynamo-electric machines have recently been presented to the Royal Society by Dr. Siemens. One of the machines examined was an ordinary medium-sized machine, substantially similar to that tried by the author in 1879. It is described as having 24 divisions of the commutator; 336 coils on the armature, with a resistance of 0·4014 Siemens units; and 512 coils on the magnets, with a resistance of 0·3065; making a total resistance of

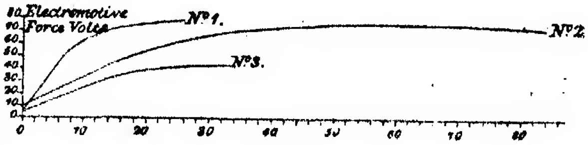

FIG. 2.

0·7079 Siemens units = 0·6654 ohms. Curve No. 2 gives the relation of electromotive force and current, reduced to a speed of 700 revolutions per minute, the actual speeds ranging from 450 to 800 revolutions. The maximum electromotive force appears to be probably 76 volts, and the critical current 15 webers, which is the same as in the author's first experiments on a similar machine.

In the summer of last year the author examined a Siemens machine of the smallest size. This machine is generally sold as an exciter for their alternate current machine. It has an internal resistance of 0·74 ohms, of which 0·395 is in the armature or helix. The machine is marked to run at 1,130 revolutions per minute. The following Table gives, for a speed of 1,000 revolutions, the total resistance, current, electromotive force, and horse-power developed as current. The horse-power expended was not determined:—

Experiments on smallest-sized Siemens Dynamo-Electric Machine

Resistance. Ohms.	Electric current. Webers.	Electromotive force. Volts.	Horse-power developed as current. H. P.
2·634	4·53	13·2	0·08
2·221	10·8	27·0	0·39
1·967	15·1	33·6	0·68
1·784	18·1	36·4	0·88
1·668	19·8	37·2	0·98
1·579	20·6	36·6	1·01
1·503	22·8	39·3	1·20
1·440	24·7	40·0	1·32
1·145	32·2	41·5	1·79

Curve No. 3 gives as usual the relations of electromotive force and current. From this curve it will be seen that the critical current is 11·2 webers, and the maximum electromotive force, at the speed of 1,000 revolutions, is about 42 volts. The determinations for this machine were made in exactly the same manner as in the experiments on the medium-sized machine, using the galvanometer, but omitting the experiment with the calorimeter (compare Table I., p. 249, *Proceedings*, April, 1879).

The time required to develop the current in a Gramme machine has been examined by Herwig (Wiedemann, June, 1879). He established the following facts for the machine he examined. A reversed current, having an electromotive force of 0·9 Grove cells, sufficed to destroy the residual magnetism of the electro-magnets. If the residual magnetism was as far as possible reduced, it took a much longer time to get up the current than when the machine was in its usual state. A longer time was required to get up the current when the external resistance was great, than when it was small. With ordinary resistance the current required from ¾ second to 1 second to attain its maximum.

Brightness of the Electric Arc.—The measurement of the light emitted by an electric arc presents certain peculiar difficulties. The light itself is of a different colour from that of a standard candle, in terms of which it is usual to express luminous intensities. The statement, without qualification, that a certain electric lamp and machine give a light of a specified number of candles, is therefore wanting in definite meaning. A red light cannot with propriety be said to be any particular multiple of a green light; nor can one light, which is a mixture of colours, be said with strictness to be a multiple of another, unless the proportions of the colours in the two cases are the same. Capt. Abney (*Proceedings* of the Royal Society, March, 1878) has given the

[1] Paper read at the Institution of Mechanical Engineers, by Dr. John Hopkinson, F.R.S.

results of measurements of the red, blue, and actinic light of electric arcs, in terms of the red, blue, and actinic light of a standard candle. The fact that the electric light is a very different mixture of rays from the light of gas or of a candle, has long been known, but has been ignored in statements intended for practical purposes.

Again, the emission of rays from the heated carbons and arc is by no means the same in all directions. Determinations have been made in Paris of the intensity in different directions, in particular cases. If the measurement is made in a horizontal

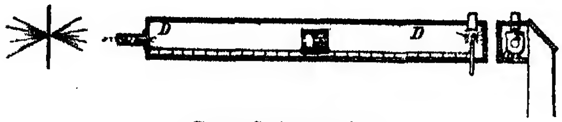

FIG. 3 (Scale about $\frac{1}{30}$).

direction, a very small obliquity in the crater of the positive carbon will throw the light much more on one side than on the other, causing great discordance in the results obtained.

If the electric light be compared directly with a standard candle, a dark chamber of great length is needed—a convenience not always attainable. In the experiments made at the South Foreland by Dr. Tyndall and Mr. Douglass, an intermediate standard was employed; the electric light was measured in terms of a large oil lamp, and this latter was frequently compared with a standard candle.

Other engagements have prevented the author from fairly attacking these difficulties; but since May 1879 he has had in occasional use a photometer with which powerful lights can be measured in moderate space. This photometer is shown in Fig. 3, and an enlargement of the field-piece in Fig. 4. A lens

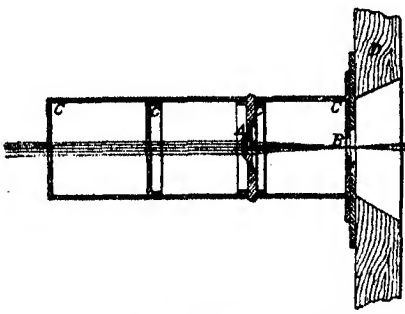

FIG. 4 (Scale about $\frac{1}{2}$).

A, of short focus, forms an image at B of the powerful source of light which it is desired to examine. The intensity of the light from this image will be less than that of the actual source by a calculable amount; and when the distance of the lens from the light is suitable, the reduction is such that the reduced light becomes comparable with a candle or a carcel lamp. Diaphragms CC are arranged in the cell which contains the lens, to cut off stray light. One of these is placed at the focus of the lens, and has a small aperture. It is easy to see that this diaphragm will cut off all light entering from a direction other than that of the source; so effectually does it do so, that observations may be made in broad daylight on any source of light, if a dark screen be placed behind it. The long box DD, Fig. 3, of about 7 feet length, is lined with velvet—the old-fashioned dull velvet—not that now sold with a finish, which reflects a great deal of the light incident at a certain angle. This box serves as a dark chamber, in which the intensity of the image formed by the lens is compared with a standard light, by means of an ordinary Bunsen's photometer E, sliding on a graduated bar.

Mr. Dallmeyer kindly had the lens made for the author: he can therefore rely upon the accuracy of its curvature and thickness; it is plano-convex, the convex side being towards the source of light. The curvature is exactly 1 inch radius, and the thickness is 0·04 inch; it is made of Chance's hard crown glass, of which the refractive index for the D line in the spectrum is 1·517. The focal length f is therefore 1·933 inch.

Let u denote the distance of the source of light from the curved surface of the lens, and v the distance of the image of the source B from the posterior focal plane. Neglecting for the moment loss by reflection at the surface of the glass, the intensity of the source is reduced by the factor $\left(\frac{v}{u}\right)^2$. But $\frac{1}{v} + \frac{1}{u} = \frac{1}{f}$, or $v = \frac{uf}{u - f}$; hence the factor of reduction is $\left(\frac{f}{u - f}\right)^2$. The effect of absorption in so small a thickness of very pure glass may be neglected; but the reflection at the surfaces will cause a loss of 8·3 per cent. which must be allowed for. This percentage is calculated from Fresnel's formulæ, which are certainly accurate for glasses of moderate refrangibility, and for moderate angles of incidence.

Suppose, for example, it is required to measure a light of 8,000 candles; if it be placed at a distance of 40 inches it will be reduced in the ratio 467 to 1, and becomes a conveniently measurable quantity. By transmitting through coloured glasses both the light from an electric lamp and that from the standard, a rough comparison may be made of the red or green in the electric light with the red or green in the standard.

A dispersive photometer, in which a lens is used in a somewhat similar manner, is described in Stevenson's "Lighthouse Illumination." Messrs. Ayrton and Perry described a dispersive photometer with a concave lens at the meeting of the Physical Society on December 13, 1879 (*Proc.* of the Physical Society, vol. iii. p. 184). The convex lens possesses however an obvious advantage in having a real focus, at which a diaphragm to cut off stray light may be placed.

Efficiency of the Electric Arc.—To define the electrical condition of an electric arc, two quantities must be stated: the current passing, and the difference of electric potential at the ends of the two carbons. Instead of either one of these, we may, if we please, state the ratio $\frac{\text{difference of potential}}{\text{current}}$, and call it the resistance of the arc, that is to say, the resistance

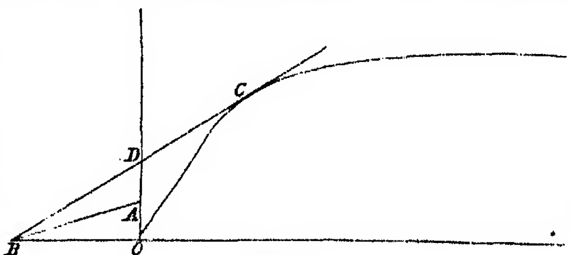

FIG. 5.

which would replace the arc without changing the current. But such a use of the term electric resistance is unscientific; for Ohm's law, on which the definition of electric resistance rests, is quite untrue of the electric arc; and, on the other hand, for a given material of the electrodes, a given distance between them, and a given atmospheric pressure, the difference of potential on the two sides of the arc is approximately constant. The product of the difference of potential and the current is of course equal to the work developed in the arc; and this, divided by the work expended in driving the machine, may be considered as the efficiency of the whole combination. It is a very easy matter to measure these quantities. The difference of potential on the two sides of the arc may be measured by the method given by the author in his previous paper, by an electrometer, or in other ways. The current may be measured by an Obach's galvanometer, by a suitable electro-dynamometer, or best of all, in the author's opinion, by passing the whole current, on its way to the arc, through a very small known resistance, which may be regarded as a shunt for a galvanometer of very high resistance, or to the circuit of which a very high resistance has been added.

It appears that with the ordinary carbons and at ordinary atmospheric pressure no arc can exist with a less difference of potential than about 20 volts; and that in ordinary work, with an arc about $\frac{1}{4}$ inch long, the difference of potential is from 30 to 50 volts. Assuming the former result, about 20 volts, for the difference of potential, the use of the curve of electromotive forces may be illustrated by determining the lowest speed at which a given machine can run, and yet be capable of producing a short arc. Taking O as the origin of co-ordinates, Fig. 5, set off upon the axis of ordinates the distance OA equal to 20 volts; draw AB to intersect at B the negative prolongation of the axis

of abscissæ, so that the ratio $\frac{OA}{OB}$ may represent the necessary metallic resistance of the circuit. Through the point B, thus obtained, draw a tangent to the curve, touching it at C, and cutting OA in D. Then the speed of the machine, corresponding to the particular curve employed, must be diminished in the ratio $\frac{OD}{OA}$, in order that an exceedingly small arc may be just possible.

The curve may also be employed to put into a somewhat different form the explanation given by Dr. Siemens at the Royal Society respecting the occasional instability of the electric light as produced by ordinary dynamo-electric machines. The operation of all ordinary regulators is to part the carbons when the current is greater than a certain amount, and to close them when it is less; initially the carbons are in contact. Through the origin O, Fig. 6, draw the straight line OA, inclined at the angle

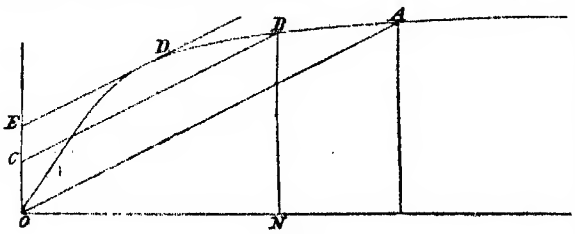

FIG. 6.

representing the resistances of the circuit other than the arc, and meeting the curve at A. The abscissa of the point A represents the current which will pass if the lamp be prevented from operating. Let ON represent the current to which the lamp is adjusted; then if the abscissa of A be greater than ON, the carbons will part. Through N draw the ordinate BN, meeting the curve in the point B; and parallel to OA draw a tangent ED, touching the curve at D. If the point B is to the right of D, or farther from the origin, the arc will persist; but if B is to the left of D, or nearer to the origin, the carbons will go on parting, till the current suddenly fails and the light goes out. If B, although to the right of D, is very near to it, a very small reduction in the speed of the machine will suffice to extinguish the light. Dr. Siemens gives greater stability to the light by exciting the electromagnets of the machine by a shunt circuit, instead of by the whole current.

The success of burning more than one regulating lamp in series depends on the use in the regulator of an electro-magnet, excited by a high-resistance wire connecting the two opposed carbons. The force of this magnet will depend upon the difference of potential in the arc, instead of depending, as in the ordinary lamp, upon the current passing. Such a shunt magnet has been employed in a variety of ways. The author has arranged it as an attachment to an ordinary regulator; the shunt magnet actuates a key, which short-circuits the magnet of the lamp when the carbons are too far parted, and so causes them to close.

In conclusion the author ventures to remind engineers of the following rule for determining the efficiency of any system of electric lighting in which the electric arc is used, the arc being neither exceptionally long nor exceptionally short. Measure the difference of potential of the arc, and also the current passing through it, in volts and webers respectively; then the product of these quantities, divided by 746, is the horse-power developed in that arc. It is then known that the difference between the horse-power developed in the arc and the horse-power expended to drive the machine must be absolutely wasted, and has been expended in heating either the iron of the machine or the copper conducting wires.

PRELIMINARY REPORT BY THE COMMITTEE ON SOLAR PHYSICS APPOINTED BY THE LORDS OF THE COMMITTEE OF COUNCIL ON EDUCATION

"SIR,—In reply to Mr. MacLeod's letter of November 20, 1879, calling upon us, pending the preparation of our General Report, to give a brief summary of the progress already made, and to state at the same time what work was in hand, and such other facts as we might think it desirable to mention, to enable their Lordships to determine whether they shall apply to the Lords Commissioners of Her Majesty's Treasury for an extension of the vote for another year, we have the honour now to submit the following report.

"The Committee have had thirteen formal meetings. In addition to this several members of the Committee have carried out special branches of the inquiry; and Mr. Lockyer, as arranged when the Committee was appointed, has been charged with the general conduct of the observational and experimental work at South Kensington. The Committee consider that Mr. Lockyer by his laboratory work and comparison of the results with solar phenomena, has brought together a great body of evidence tending *primâ facie* to conclusions of the utmost importance. The labour and difficulty of the research are, however, so great that much additional time and attention must continue to be bestowed on it before the questions thus raised can be considered as finally settled; and the Committee think it of much importance that the researches now being carried on should not be interrupted.

"The Committee have been in correspondence with the Indian Government, the Astronomer-Royal, the Directors of the Observatories at Wilna, Melbourne, Mauritius, Kew, Moscow, Toronto, Paris, Palermo, Princeton, and with Dr. Warren De la Rue. From all of these promises of valuable co-operation and assistance have been received. To the Astronomer-Royal our thanks are specially due for the manner in which he has met us in the matter, placing all the information bearing on the subject in the Royal Observatory at our service.

"A few months before the appointment of the Committee, daily photographs of the sun had been commenced by order of the Government of India under the Surveyor-General at Dehra, N.W. Provinces, the photographs being transmitted to Mr. Lockyer for reduction.

"Unfortunately the observer, Mr. Meins, late of the R.E., sent from this country, after having been trained at Chatham and South Kensington, died suddenly in the early part of the year, and the continuity of the daily record was thus broken. In August the Government of India requested to be informed as to the importance of the continuance of the records thus interrupted, and the following letter was sent in reply:—

"'*Science and Art Department, London, S.W.,*
"'*27th November*, 1879

"'SIR,—In reply to your letter dated August 10, 1879, inviting remarks relative to the importance of continuing certain solar observations which were recently instituted in India, and suggestions as to future arrangements if it should be decided that the observations are to be continued for an indefinite period, I beg leave to submit to you, for the information of Lord Cranbrook, the following explanation:—

"'In their General Report the Science Commissioners recommended the establishment of a system of physical (as distinguished from astronomical) observations on the sun, and pointed out the advantages which Northern India offers for this study. A memorial was more recently presented to Government, signed by a number of our leading scientific men, urging the carrying out of this recommendation.

"'In compliance with these recommendations the British Government as a preliminary step appointed a Committee on Solar Physics, whose duty it should be to make trial of methods of observation, collect observed results, &c., and who were specially charged with the reduction of such observations as should be made in India. As a consequence of this arrangement the Government of India authorised the employment of the late Mr. Meins for the purpose of taking photographs of the sun in India, and a series of such photographs was prepared by him and has been sent home to be dealt with. The following brief statement will show how superior the climate of India is to our own for observations of this kind. The Astronomer-Royal has been so kind as to furnish the Committee with a list of the solar photographs taken at the Royal Observatory during the period 21st July, 1873, to 18th July, 1879, over a part of which Mr. Meins' work extended. It should be mentioned that in both places alike the rule was to take three photographs daily, in the morning, about noon, in the afternoon, when clear views of the sun could be obtained. In the rare cases in which a fourth photograph was taken in the same day in India, it is not included in the following list:—

		Greenwich.	India.
Total number of days during which both instruments were working simultaneously between February 11th, 1878, and March 31st, 1879	384		
Total number of photographs. Reducing where four or more have been taken to three		207	872
Number of days on which one at least was taken		143	342
Number of days on which no photograph was taken		244	42

"'No correction has been made for the non-taking of photographs at Greenwich on Sundays.

"'In the total number of photographs the maximum number taken on any one day has been taken as three.

"'The actual returns are inclosed as an appendix B and C.[1]

"'It so happens that for the last year or two the sun has been in a condition of unusual quiescence, so that in the whole series of photographs sent home by Mr. Meins there were only two or three small spots. But it is well established by previous experience that the sun passes alternately through a condition of few spots and many spots, the whole period of the change being about eleven years. We are now, according to the reckoning, entering on a period of solar activity, and already spots have begun to appear. The present time and the immediate future form therefore a period of special interest for the observation of solar phenomena. And though the immediate object of the memorialists in advocating a more active study of solar physics was an increase to our scientific knowledge, it is hard to say what bearings such an increase may not have upon the practical concerns of life. There is some reason to think that meteorological conditions bear traces of a period similar to that of solar activity as manifested by spots, and it has been conjectured that the droughts and consequent famines which from time to time have devastated portions of our Indian Empire show something of a similar period. Should a further study of solar phenomena lead to even an approximate forecast of the liability to such terrible visitations, it is needless to say of what practical importance it would thereby become.

"'As has been already explained the Committee, were appointed as a temporary measure to prepare the way for something of a more permanent and systematic nature, and it is to aid them in this work that the Indian observations have been asked for. What shape the research may permanently take it is impossible at the present time to predict.

"'In view of these facts the Committee is of opinion that it is of special importance that the series of Indian sun photographs should be resumed as early as practicable, if, as is feared, they have been interrupted, and should be continued without break at all events for three or four years to come, the present period of increasing solar activity being one of peculiar scientific interest.

"'The Committee further suggest that the Surveyor-General of India, under whom Sergeant White, the successor of Mr. Meins, will be employed, might usefully be instructed to cause one or more native *employés* of the Survey Department to be instructed in the process of solar photography, so that risk of interruption of the series from sickness, &c., of the European photographer may be guarded against in the future.

"'It is believed that skill in the necessary manipulations for successful photography could be readily acquired by intelligent natives, and that when this had been done further assistance from this country for the supply of photographers would not be needed.

"'I have the honour to be, Sir,
"'Your obedient servant,
"'(Signed) "'G. G. Stokes'

"Considerations in all respects identical with those which we thought of weight in regard to India are in our opinion generally applicable, and we have no hesitation in expressing our belief that the continued careful study of the class of phenomena in question will prove to be of the greatest scientific value, and that there is no reason for doubting that the advance of true knowledge in this direction will, in some form or other, and sooner or later, prove to be of real practical value also, as all experience has shown that it has been in other branches of human knowledge.

[1] It has not been considered necessary to reproduce these appendices in this place.

"Whether or not we shall ever possess the power of foreseeing the character of the seasons in this country, or to what extent they may in truth be related to those changes in the condition of the sun to which our attention is specially directed, it is of course impossible for us to say. But of the extreme importance of doing all that lies in our power to advance a sound knowledge of the laws of climate which so directly affect the well-being of the whole human race there can be no question.

"We append details of the work in which we have been engaged.

"G. G. Stokes
Balfour Stewart
Richard Strachey
J. Norman Lockyer
W. de W. Abney
J. F. D. Donnelly

"The Secretary, Science and Art Department"

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

Cambridge.—It appears rather noteworthy that at a very recent debate in the Cambridge Union (May 4), a motion proposed by Mr. Theodore Beck, of Trinity College, affirming that the Tripos system of education here adopted is unfavourable to the interests of original research and individual culture, should have been lost by only three votes, after speeches in opposition to the motion in which more than one distinguished Tripos man took part. The votes were: For the motion, 51; against, 54.

Mr. E. Temperley, of Queen's College, and Mr. W. Burnside, of Pembroke College (on the nomination of Corpus Christi College), have been appointed Moderators for the next Mathematical Tripos.

It appears from the discussion on the subject of the exemption from Greek of honours students who desire exemption, and offer French and German, that there is much diversity of opinion on the subject, even among residents. How long will it be before the ideas of freedom have practical effect in Cambridge? Dr. Thompson, Master of Trinity, was strongly desirous that Greek should not be required of men coming to Cambridge as serious students of mathematics and natural science. He had no wish to weaken the position of Greek, but to allow men to come to the University and obtain distinction in their own line. Prof. Skeat wondered why a knowledge of English language and literature could not yet find a place in the course for the Little-go; the University had very few studying or capable of teaching it in a scientific way. Mr. Henry Jackson said the present system put many boys through the drudgery of learning the rudiments to get the chance of making classical scholars of a few. Mr. Vansittart gave expression to the regret of many that it should be proposed to substitute two languages for Greek; he would give as alternatives natural sciences for mathematical men, and additional mathematics for natural science men, or he would leave the choice between English and natural sciences.

It is to be hoped that Cambridge University will cease from the fruitless attempt to find out one universal mode of culture and routine for schools. The Local Examinations Syndicate have already done this, not having to secure the approbation of the entire Senate for all the alternative subjects it offers. But the Public Schools follow too much the lead of the Pass Examinations in the Universities. The Syndicate, considering the question, have referred very much to the opinions of head-masters of public schools, and because they feel so much that their "craft" is in danger, the great need of gaining the mass who do not go to public schools may be lost sight of.

The late Mr. John Henry Challis bequeathed 100,000*l.* to the University of Sydney. Its Parliamentary assistance is only 5,000*l.* per annum, a sum quite insufficient to secure as many Chairs in the different faculties as the name of University implies. The bequest of Mr. Challis, invested at 5 per cent., will add another 5,000*l.* per annum to the sum voted by Parliament, and will enable the faculties to enlarge their curriculum and extend their operations in a manner they have never yet had the means to attempt.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 22.—"On the Critical State of Gases." By William Ramsay, Ph.D., Professor of Chemistry in University College, Bristol.

It is well known that at temperatures above that which produces what is termed by Dr. Andrews the "critical point" of a liquid, the substance is supposed to exist in a peculiar condition, and Dr. Andrews purposely abstained from speculating on the nature of the matter, whether it be liquid or gaseous, or in an intermediate condition, to which no name has been given. As my observations bear directly on this point, it may be advisable first to describe the experiments I have made, and then to draw the deductions which appear to follow from them.

A piece of barometer tubing about three inches long was sealed at one end and drawn into a capillary tube at the other; after being filled with methyl formate it was exhausted, and after two-thirds of the ether had evaporated was sealed. By this means all air was removed from the tube, which contained merely the ether and its vapour.

1. On applying heat the temperature gradually rose to 221°·5 (corr.); during the rise the meniscus of the liquid gradually became less curved, and at the above-mentioned temperature disappeared. On cooling to 218° a mist was seen at the point where the meniscus had disappeared, and the meniscus shortly afterwards became again visible.

2. Two similar tubes were prepared, one containing less and the other more of the same ether; the point at which the meniscus disappeared in the former was 228°, and in the latter 215°.

3. A tube of the shape shown was filled to the mark with methyl formate and heated in an inclined position, the portion containing the liquid being the lower. The liquid, as usual, expanded, and at the moment when the meniscus disappeared it nearly filled the lower half. The source of heat was then withdrawn, and on cooling the liquid all condensed in the *lower* half.

4. The last experiment was varied by tilting the tube after the meniscus of the liquid had disappeared, so that that half which had contained the liquid was uppermost. On cooling, the liquid condensed in the *upper* half of the tube.

5. The experiment was again varied by keeping the tube at a temperature a few degrees above the point where the meniscus vanished, for half an hour. On cooling, an almost equal quantity had condensed in each division of the tube. (During Experiments 3, 4, and 5, great care must be taken to keep the heater from draughts of cold air, otherwise unequal cooling results and distillation takes place.)

6. It was noticed that that half of the tube containing liquid, after the meniscus had vanished, appeared *full*, while the other half of the tube seemed to be *empty*. The refractive indices of the fluid contained in the tubes were therefore different. The portion of the tube containing liquid was shown to be a more powerful cylindrical lens than the empty portion, for on focussing a spot behind the tube with a microscope, the focus was shorter when the portion which had contained liquid was placed between the microscope and the spot than when the portion appearing empty was interposed.

7. From experiments on the expansion of liquids above their boiling-points, of which numerical details shall be given on a future occasion, it appears probable that the specific gravity of the hot liquid, at the temperature at which the meniscus vanishes, is identical with that of the compressed gas evolved from the liquid. This has also been noticed by Ansdell in two cases, viz., hydrogen chloride and acetylene.

8. From observations on the expansions of liquids at high temperatures it has been proved that liquids above the temperatures at which their menisci vanish are not uniformly compressible.

From these observations I would draw the following inferences:—When a liquid is heated under pressure it expands, and at the same time evolves vapour. The vapour gains in specific gravity, while the specific gravity of the liquid is rapidly diminishing. *The critical point is that point at which the liquid, owing to expansion, and the gas, owing to compression, acquire the same specific gravity, and consequently mix with one another.* From the first experiment it is seen that, on cooling, the liquid contracts more rapidly than the gas, and consequently separates as a mist through the whole of the tube, and, from its gravity, separates at the lower half. The second experiment shows that when the tube contains a small amount of liquid the space left for gas is larger, and consequently more vapour must be given off by the liquid before enough gas can be compressed till it acquires the same specific gravity as the liquid; the temperature at which the meniscus disappears is consequently higher. If the space left for gas be smaller, the opposite is the case. The fourth, fifth, sixth, and seventh experiments demonstrate that by suitable means it is possible to prevent, or rather to retard, the mixing of gas and liquid. They then retain their several refractive indices. If, however, time be allowed for diffusion through the capillary tube, the whole becomes homogeneous, and the refractive indices of the fluids contained in either portion of the tube are then identical.

So long as gas is being compressed, pressure rises gradually with decrease of volume, whereas, even above their critical points, liquids are comparatively incompressible.

In conclusion, let me refer to a paper communicated to the Society by Messrs. Hannay and Hogarth last October, entitled "On the Solubility of Solids in Gases." Should the views of the subject suggested by the above experiments be correct, it follows that these gentlemen have observed nothing unusual, but

merely the ordinary phenomenon of solubility of a solid in a hot liquid. This view is borne out by their own experiments. They found that on reducing pressure, that is, on allowing the liquid to change to gas, the solid precipitated; and also on heating the tube containing the solution locally, that is, by converting the liquid near the heated point into gas, precipitation took place. I have taken the liberty of repeating one of their experiments with a slight modification.

A tube shaped like that used in Experiment 3, after a small fragment of potassium iodide had been placed in the lower compartment, was filled with nearly anhydrous alcohol; and after rather more than two-thirds of the alcohol had been evaporated under reduced pressure, the tube was sealed. The lower portion of the tube contained a strong alcoholic solution of potassium iodide, besides a small piece of undissolved salt. The upper portion of the tube was free from alcohol, but its walls were incrusted with a thin crystalline film of potassium iodide. The tube was heated in a sloping position, the liquid being in the lower half. After the meniscus had disappeared, the iodide in the lower half of the tube dissolved, while the film in the upper half, even in its thinnest portions, remained unchanged. On cooling, very sparkling crystals deposited in the lower half of the tube, but no glittering crystals in the upper half.

By repeated distillation the iodide in the upper portion of the tube was washed down into the lower half, and when dry the sides of the upper tube were quite bright and clean. The tube was again heated in the same position to 20° above the temperature at which the meniscus had disappeared. On cooling, the sparkling crystals again appeared in the lower tube, but not a trace in the upper tube. To eliminate all possibility of mistake the experiment was repeated five times with the same result, and finally the alcohol was distilled into the upper tube; it was then broken off, and its contents carefully tested for iodine with sodium hypochlorite and starch-paste. There was not the faintest blue colour, and it is therefore certain that potassium iodide is absolutely insoluble in alcohol vapour.

Messrs. Hannay and Hogarth also found that the absorption spectrum of coloured salts remains unaltered, even when the liquid in which they are dissolved loses its meniscus. Surely no clearer proof is needed to show that the solids are not present as gases, but are simply solutions in a liquid medium.

To eliminate any source of error dependent on the use of methyl formate, two other substances were employed, viz., carbon disulphide, CS_2, and carbon tetrachloride, CCl_4. The former of these liquids was rectified five times over sodium, and then boiled at 48·7 (corr.). The latter was rectified four times over phosphoric anhydride, and boiled constantly at 77·5 (corr.).

They yielded the following results:—

	Tube more than half full.	Tube less than half full.
CS_2	282·7	286·4
CCl_4	283·3	288·4

These readings are given for the first appearance of a cloud in the tube on cooling, and differ from the temperature at which the meniscus disappears by being about half a degree lower. They also do not represent extreme instances, for in the first cases the liquids do not entirely fill the tube, and in the second about half an inch of liquids remains in the tubes before it becomes impossible to distinguish liquid from gas.

The experiments described in a former part of this paper, relating to the difference of refraction shown by a liquid above its so-called critical point, and the gas evolved from it, were repeated with carbon tetrachloride and carbon disulphide, and held good in both cases. The phenomena observed differed in no particular from those already described.

In conclusion, a few remarks on the liquefaction of the so-called permanent gases may not be deemed out of place. If the deductions from the above experiments be correct, it follows that that form of matter which we call gas may be converted into liquid by pressure alone; but the meniscus will never become visible, for the process of change is a gradual one. To render the meniscus visible it is necessary to take advantage of the fact that liquids under such circumstances have a much greater coefficient of expansion by heat, and conversely, a much greater coefficient of contraction on withdrawal of heat, than gases. It therefore becomes necessary to lower the temperature until the liquid by contraction acquires a specific gravity greater than that of its gas, and then, and not till then, does the phenomenon of a meniscus become observable.

April 29.—"On the Diurnal Variation in the Amount of Carbon Dioxide in the Air." By George Frederick Armstrong, M.A., F.G.S., C.E., Professor of Engineering in the Yorkshire College, Leeds. Communicated by Prof. Thorpe, F.R.S.

Summarising the results contained in this communication, it may be stated—

1. That the normal amount of carbonic acid present in the air of the land is distinctly less than that usually stated, and that it does not exceed 3·5 vols. in 10,000 of air.

2. That plants absorb carbonic acid during the day and exhale it at night, and that vegetation therefore affects the quantity of carbonic acid present in the air, decreasing it by day and increasing it at night.

3. That from this cause there is, during that part of the year when vegetation is active, at least 10 per cent. more carbonic acid present in the air of the open country at night than during the day.

Chemical Society, May 6.—H. E. Roscoe, president, in the chair.—The following papers were read:—On the action of sodium on phenylic acetate, by W. H. Perkin, jun., and W. Hodgkinson. Hydrogen, acetic ether, phenol, acetic acid, salicylic acid, a white crystalline substance melting at 48° C., having the composition $C_{15}H_{12}O_3$, and a yellow crystalline substance melting at 138°, having the composition $C_{18}H_{14}O_4$, were obtained; by heating cresylic acetate and sodium, acetic ether and salicylic acid were formed.—Preliminary notice on the action of sodium on some ethereal salts of phenylacetic acid, by Dr. Hodgkinson. The first products of this action are the corresponding ethylic, &c., ethers of phenylacetic acid. The phenyl group being replaced by hydrogen, it reacts with sodium on another portion of the original ethereal salt, forming various liquid and solid bodies, which the author has investigated, but whose constitution is as yet undetermined.—On the determination of nitrogen in carbon compounds, by C. E. Groves. The author described and exhibited an improved and simple apparatus for facilitating the collection and measurement of the nitrogen evolved during the combustion of a substance according to Dumas' method.—On essential oil of sage, by M. M. P. Muir. The composition of this oil varies with its age, salviol and camphor being formed as it gets older. English sage-oil contains cedrene. The terpene of sage-oil is identical with that of French turpentine. The author has examined the action of oxidising agents, phosphorous pentachloride, and bromine.—On the presence of nitrogen in iron and steel, by A. H. Allen. By passing steam over iron at a red-heat, and also by dissolving iron in hydrochloric acid, the author has satisfactorily proved that ammonia is formed equal to 0·0041 to 0·0172 parts of nitrogen per hundred parts of iron and steel.—On the mode of application of Pettenkofer's process for the determination of carbonic acid in expired air, by Dr. W. Marcet. The author describes and figures a portable apparatus which he has successfully used in upwards of 350 determinations of carbonic acid made during some investigations on the effect of altitude on the phenomena of respiration.—On an improved form of oven for heating sealed tubes and avoiding risks of explosions, by Watson Smith.—Note on a convenient form of lead-bath for Victor Meyer's apparatus for determining the vapour-densities of high boiling substances, by Watson Smith.

Anthropological Institute, April 27.—Major-General A. Pitt-Rivers, F.R.S., vice-president, in the chair.—Edward Tyrrell Leith, LL.M., was elected a new member.—A paper entitled "Further Notes on the Romano-British Cemetery at Seaford, Sussex," by Mr. F. G. Hilton Price and Mr. John E. Price was read. It was a continuation of one read before the Institute by the same authors in November, 1876. During the summer of 1879 these gentlemen again visited Seaford, and made further excavations in the Roman Cemetery upon the Downs, in which they discovered several urns, a drinking cup of Durobrivian pottery, Samian pateræ, flint celts of the neolithic type, and many flint flakes. In one particular interment a large urn full of charred human bones was discovered, having a Samian cup in its mouth for the purpose of keeping out the earth, another cup of elegant form of Durobrivian ware was found on its left side, and a food vessel and patera of Upchurch pottery on the right side. In close proximity to this interment was a similar one; the urn was much crushed, but beneath a patera of Samian ware a coin of Faustina Junior, the daughter of Antoninus Pius and wife of Marcus Aurelius, was found. This was most important as giving an approximate date to the interments; they could not be earlier than between A.D. 161-180. In another

part of the Downs, in a place called the Little Burys, black patches were of frequent occurrence in the sand, which were composed of charcoal, fragments of burnt bone, a flint flake or two, and frequently iron nails. In one particular spot a batch of over ninety iron studs was found, mixed up with bone ashes and charcoal. The authors considered that the patches of charcoal without an urn indicated pauper burials, or the burials of soldiers, as this place was a military station. The pottery and other relics discovered were exhibited.—General A. Pitt-Rivers exhibited a series of plans and relics from Mount Caburn.

Photographic Society, April 6.—J. Glaisher, F.R.S., president, in the chair.—Mr. J. H. Dallmeyer, F.R.A.S., read a paper on principles of optics involved in lantern construction; and on a new enlarging lens especially designed for use with the magic lantern, in which he described all previous existing objective lenses and condensers and the scientific principles which ought to be observed in their construction, and then exhibited and described a new condenser he had constructed containing the essentials required, viz., quantity and quality of light; also a new objective lens which gave equal definition at the margin as well as at the centre of the picture, freedom from distortion, and perfect achromatism.—A paper was read by Capt. Abney, R.E., F.R.S., on the use of silver iodide in a *gelatino-bromide emulsion*, showing that the introduction of iodide into the ordinary gelatino-bromide emulsion did not decrease its sensitiveness, as also that it permitted the use of an ordinary yellow light to work in—same as for wet collodion.—Also a paper, by W. England, on a drying box for gelatine plates.

GÖTTINGEN

Royal Society of Sciences, January 10 (continued).—On boracite, by Herr Klein.

February 7.—The affinity-grouping of old German dialects, by Herr Bezzenberger.—On physiological retrogression of ovarian eggs in mammals, by Dr. Brunn.—On sexual propagation of *Dasycladus clavæformis*, Ag., by Herr Berthold.—The theory of numerical-theoretical functions, by Prof. Cantor.—On a class of functions of several variables which arise by inversion of the integrals of solution of linear-differential equations with rational coefficients, by Herr Fuchs.

March 6.—On the theory of partial linear differential equations, by Dr. Krankenhagen.

VIENNA

Imperial Academy of Sciences, January 22.—The following papers, &c., were read:—The Diptera of the Imperial Museum in Vienna, by Prof. Brauer.—On projectivities and involutions in plane rational curves of the third order, by Prof. Weyr.—The periods of springs, by Herr Klönne.—On the behaviour of phenanthrenchinon towards ammonia, by Prof. Sommaruga.—On chlorhydrate of morphin, by Herr Tausch.—The more recent deposits on the Hellespont, by Prof. Neumayr and Herr Calvert.—Survey of the geological relations of a part of the Ægean coast lands, by Prof. Neumayr, Dr. Bittner, and Fr. Teller.

February 5.—Communications from the Embryological Institute of Vienna University, by Prof. Schenk.—The respiratory apertures of the Marchantiaceæ, by Prof. Leitgeb.—On nectar-secreting trichomes of some species of *Melampyrum*, by Prof. Rathay.—On the yearly period of the insect-fauna of Austria-Hungary. V. Rhynchota, by Herr Fritsch.—Electric action on the form of flames, by Herr Goldstein.—On the probable errors and the available results of calculation deduced from imperfect numbers, by Dr. Rotter.—Tables of observations at the Central Institution for Meteorology and Magnetism.

PARIS

Academy of Sciences, May 3.—M. Edm. Becquerel in the chair.—The following papers were read:—On the transcendants which play a fundamental part in the theory of planetary perturbations, by M. Tisserand.—On the gases retained by occlusion in aluminium and magnesium, by M. Dumas. While silver imprisons oxygen, aluminium and magnesium specially retain hydrogen. The substances were heated to a high temperature *in vacuo*. The 89·5 c.c. gas given off by 200 gr. aluminium (representing 80 c.c.) at 17° and 755 mm., contained 1·5 c.c. CO_2 and 88·0 c.c. H.; 20 gr. magnesium gave 12·3 c.c. H. and 4·1 c.c. CO. (In another case there was both CO and CO_2.) The whole of the magnesium was volatilised and condensed in stalactites (in great purity) about the neck of the retort.—On the cholera of fowls; study of the conditions of non-recurrence of the malady, and of some others of its characters, by M. Pasteur. The extract of a filtered culture-liquid of the microbe, when injected, produces sleep (for a time); the microbe seems to generate a narcotic during its life. This effect is independent of disorders produced by multiplication of the parasite in a fowl's body. The malady sometimes occurs in a chronic form.—On extension of the theory of germs to the etiology of some known maladies, by M. Pasteur. He shows reasons for attributing boils, osteomyelitis, and puerperal fever to the development of minute organisms.—On a letter of Admiral Cloué relative to waterspouts, by M. Faye.—Formation of leaves and appearance of their first vessels in Iris, Allium, Funkia, Hemerocallis, &c., by M. Trécul.—On the law of reciprocity in the theory of numbers, by Prof. Sylvester.—Experimental researches on the decomposition of some explosives in a closed vessel; composition of the gases formed, by MM. Sarran and Vieille. The products are indicated in the case (1) of pure gun-cotton (this gives, per kgm. of substance, 741 litres of gas made up of 234 CO, 234 CO_2, 166 H, and 107 N), (2) of a mixture in equal parts of gun-cotton and nitrate of potash, (3) of a mixture of 40 parts gun-cotton and 60 nitrate of ammonia, (4) of nitroglycerine, (5) of ordinary blasting-powder.—Cometary paraboloids, by Mr. Chase.—On simultaneous linear equations, and on a class of non-plane curves, by M. Picard.—On Gauss's formula of quadrature, by M. Callandreau.—Theorem on cubic and biquadratic equations, by M. Desboves.—General equation giving the relation which exists for all liquids between their temperature and the maximum tension of their vapours at this temperature, by M. Pictet.—*Résumé* of the laws which rule matter in the spheroidal state, by M. Boutigny. The fifth law, that of repulsive force at a sensible distance, is represented as the most important, because antagonistic to universal attraction. Non-volatile bodies (as pieces of wax, tallow, stearic or margaric acid, &c.), are suspended in a heated capsule, *without vapour or gas* arising from their decomposition. Water dropped, *e.g.*, from the top of the Pantheon, 70 m. high, on a heated capsule at the bottom, is repelled instantaneously by the repulsive force generated by the heat in the capsule.—Dissociation of the hydrate of butyl-chloral, by MM. Engel and Moitessier. They find here a new confirmation of the law they formulated; the dissociation of a body whose two components are volatile does not take place in presence of the vapour of one of the components at a tension above that of dissociation of the compound.—On the determination of glycerine in wines, by M. Raynaud.—On legumine, by M. Bleunard.—On gelose, by M. Porumbaru.—Variations of temperature with the altitude for the great colds of December, 1879, in the valley of the Seine, by M. Lemoine. The data agree with those lately given by M. Alluard.—On the variability of teats in the ovides of the Lower Cevennes, by M. Tayon.—On the structure of some Corallidæ, by M. Merejkowsky.—On the analogies which seem to exist between cholera of fowls and nelavan, or the malady of sleep, by M. Déclot.

THURSDAY, MAY 20, 1880

THE SCIENCE OF LANGUAGE

Introduction to the Science of Language. By A. H. Sayce, Deputy Professor of Comparative Philology in the University of Oxford. Two vols. (London: Kegan Paul and Co., 1880.)

THIS admirable treatise may be broadly described as the fitting complement and sequel to the author's "Principles of Comparative Philology." The method and theories of that work, as he is careful to remind us in the preface, form the solid basis of the present, and it is not saying too much to add that both together stand unrivalled as the most systematic and exhaustive treatise on the Science of Language in its present state that has yet appeared in our literature. At the same time the present work is sufficiently complete in itself to be read with pleasure and studied with profit by those who may be unacquainted with its forerunner, though this must still remain indispensable to a thorough grasp of the subject.

The author shrewdly remarks (i. 159) that "the comparative philologist should not introduce the frame of mind of the specialist into his comparative inquiries. The specialist who takes up comparative philology as a subsidiary pursuit is likely to spoil it in the taking." Being thus forewarned against an obvious danger, he has not yielded to the temptation of giving undue prominence to any particular branch, nor has he allowed his personal partiality for Assyrian studies in any way to interfere with the broad and catholic spirit pervading the whole work. This catholic spirit, constituting one of its special merits, is everywhere conspicuous, and nowhere more so than in his comprehensive classification of comparative philology into the three great divisions of phonology, sematology, and morphology (i., 141). This classification at once gives its due position to that more spiritual, though hitherto almost totally neglected, aspect of the subject which deals with the inner meaning, as phonology does with the outward or material sound of words. The difficulties associated with this branch, for which the happy term sematology is here adopted, are fully recognised; its somewhat vague and uncertain character, and the intricate psychological phenomena surrounding it, all receive due prominence. But a limit is assigned to the arbitrary and to the element of chance, and if a science of sematology is not already established on a solid basis, the course that research must take in this direction is at all events ably foreshadowed. The delicate modifications of meaning that words undergo in their historic life must be carefully noted, the general causes underlying them analysed and formulated, significant change reduced to definite principle and broadly generalised.

His philosophic classification of his subject enables the writer satisfactorily to settle a point still much discussed by philologists. Whether language is to be grouped with the natural or historical sciences is a question which, he justly remarks, has arisen from the partial views that have been taken of its true character. Speech is not mere sound, nor even articulate sound alone, for many animals can articulate, but articulate sound significant. *Terminus*, said the schoolmen, *est vox significans*, and for Mr. Sayce the terminus or "word," as here used, is speech, for the isolated term has no independent or abstract existence, and the unit of speech is not the word, but the sentence. It thus becomes impossible to separate the sound from its meaning, phonology from sematology. But phonology, or the outward aspect of language, is confessedly physiological, and subject to purely physical or natural laws, while sematology is essentially historical. And so the whole difficulty is solved; for "if we claim for the science of language in general the rank of a historical science, it is only because the meaning, rather than the sound, is the essence of speech, and phonology the handmaid and instrument rather than the equivalent of glottology" (i. 165). But "the method pursued by the science of language is the method of physical science; and this, combined with the fact that the laws of sound are also physical . . . has occasioned the belief that the science of language is a physical science. But such a view results in identifying phonology and glottology, in making a subordinate science equivalent to the higher one, and in ignoring all those questions as to the nature and origin of language which are of supreme importance to the philosophy of speech" (*ib.*).

In the chapter devoted to the morphology of speech the attempt made by Hovelacque and some other recent writers to identify polysynthesis with agglutination receives no countenance. That attempt could obviously lead to nothing but hopeless confusion, for "the conception of the sentence that underlies the polysynthetic dialects is the precise converse of that which underlies the isolating or the agglutinative groups" (i. 126). This question has been elsewhere dealt with somewhat fully by this writer,[1] and it is to him a source of no little satisfaction to find his views here so fully endorsed. At the same time it seems difficult to accept the author's theory that polysynthesis is "the undeveloped sentence of primitive speech," and that "the polysynthetic languages of America preserve the beginnings of grammar, just as the Bushman dialects have preserved the beginnings of phonetic utterance" (ii. 216). For it is hard to believe that primeval man began to speak in "sesquipedalia verba," and in any case the presence of true pronouns in these lengthy sentence-words is alone sufficient to show that polysynthesis is itself a development, the outcome of slow fusion and of long ages of gradual phonetic decay. The Bushman clicks form very probably a connecting-link between articulate and inarticulate utterance. But the pronoun in all languages stands on a far higher relative level; it cannot be conceived as a primordial cut-and-dry invention, for it is an abstraction of a high order, whereas the first beginnings of speech must all have been made up of the crudest concrete concepts combined with involuntary or mechanical ejaculations.

But one of the peculiar charms of the present work is the extreme fairness of the author, who is always ready to recognise the cogency of objections to favourite theories, so that the reader feels that both sides of the question have been fairly placed before him. A good instance occurs at p. 209 of vol. i., where the weakness of Sagard's

[1] In Appendix to the "Central and South America" of "Stanford's Compendium."

testimony to the evanescent character of the Huron language is frankly acknowleged. Many other moot questions are touched with great impartiality, and it is well remarked that divergence of opinion is a healthy sign of life and scientific progress; for "it is only by the conflict and discussion of theories that truth can finally be reached, and the many controversies excited by the science of language show how broadly and deeply the foundations of the science are being laid" (i. 87).

A statement, however, is made a little further back which will perhaps cause some surprise, as tending to shake these very foundations and call in question conclusions that seemed almost universally accepted. The theory of evolution, which may be said to underlie all modern thought, and which has already passed almost beyond the pale of discussion, has naturally tended to remove much of the confusion previously associated with the various conflicting opinions entertained regarding the origin of human speech. For if true at all it is evident that this great principle must be of universal application, and when applied to language the inference was irresistible that there can be no immutable types of speech, any more than there are immutable animal and vegetable species. Hence the necessary conclusion that all present forms of speech are modifications of previously existing forms, that, however slowly, all are continually shifting, possibly retrograding under unfavourable conditions, but in the normal state advancing, for the history of evolution is on the whole the history of progress. A careful study of the texture of speech seemed fully to confirm these *à priori* deductions, and a general consensus was thus arrived at that there must have been some hypothetical root-state out of which language was slowly evolved, passing successively through lower to higher types, from the isolating to the polysynthetic, agglutinating, incorporating, inflectional, and analytic orders.

But in seeming opposition to these views the author holds that it cannot be proved that the primæval root-language ever existed, and that "equally unproved is the belief that isolating dialects develop into agglutinative, and agglutinative into inflectional" (p. 75). And at p. 131, while admitting the general doctrine of evolution, he seems still to argue for the immutability of linguistic types, though his language is here somewhat deficient in its usual clearness and point. "The Finnic idioms," he writes, "have become so nearly inflectional as to have led a recent scholar to suggest their relationship to our Aryan group; nevertheless they have never cleared the magical frontier between flection and agglutination, hard as it may be to define, since to pass from agglutination to inflection is to revolutionise the whole system of thought and language and the basis on which it rests, and to break with the past psychological history and tendencies of a speech."

Here it should be observed that the author may not inconsistently deny the necessary development of agglutination into inflection, because he does not regard the latter as a higher type than the former, and because he takes, not the word or root, but the sentence, as the unit and starting-point of all speech. Now the sentence may have been originally cast in an agglutinative form, and if so agglutination would neither imply development in itself nor any necessary further evolution in a new direction. This, at least, we take to be the underlying argument, though it appears nowhere explicitly stated in this way. It is stated, however (p. 131), that by taking the sentence as the unit "there is no longer any difficulty in distinguishing between the several families of speech and assigning to each its character and place."

To all this many will of course reply that to take the sentence as the starting-point is to beg the whole question. It cannot, of course, be denied by the consistent evolutionist that there must have been a time when a single articulate utterance supplemented by tone and gesture, did duty for a whole sentence, and in this sense it may be admitted that the sentence is the starting-point of speech. But whether this incipient state can be regarded as constituting language, properly so called, is quite another matter, and in any case it could not be predicated of such language that it was either agglutinating or polysynthetic, or even isolating in the sense that Chinese or Annamese is isolating. Here we are, in fact, dealing rather with the germs of the plant than with the plant itself.

It will further be urged that if "the Finnic idioms have become so nearly inflectional," progress from agglutination in the direction of inflection is admitted, in which case the fact that "they have never cleared the magic frontier" becomes what the French would call a mere detail, a question of time or other circumstances. The Magyar has already developed an article, and the Dravidian tongues possess what look remarkably like true case-endings, while more than one language of the Caucasus, notably Georgian, Chechenz, and Lesghian, have apparently passed quite over to the inflecting state. The fact that this transition "revolutionises the whole system of thought and language" will not alarm those evolutionists who necessarily hold that revolution is the law of nature and the order of the universe. Only the great issues are worked out *sensim sine sensu*, and not by violent cataclysms and fresh creations, as was formerly supposed by unorthodox interpreters of a book which allows of but one creation and one partial cataclysm. Lastly, the critical analysis of agglutination, and still more of inflection, clearly shows that both are the result of sematological and phonetic decay continued over immense periods of time, during which numbers of concrete terms and notional words of all sorts gradually lost their independence, and thus became transformed to relational particles first loosely tacked on (agglutination), and then completely fused (inflection) with the theme. Thus it is that the passing vagaries of deep thinkers serve but to re-establish on firmer ground the very truths they seem to assail.

On other questions the work is equally suggestive, and there are some trenchant remarks at p. 349 of vol. i. which ought definitely to close the doors of the old school of etymologists. "The etymologist must be thoroughly trained in the principles of scientific philology. He must have mastered both phonology and sematology, and he must be well acquainted with more than one of the languages with which he deals. Then and then only can his labours be fruitful; then and then only will his work be a gain and not a hindrance. False etymologies stand in the way of true ones, and the charlatans who have brought the name of etymology into contempt have

discredited the labours of better men. There is much in etymology which must always defy analysis, there is much which will have to be corrected hereafter, but this will matter little if we have once learnt the lesson that change of sound and meaning can only take place in accordance with fixed and invariable law. Etymology is but a means to an end, and that end is partly the history of the development of thought and civilisation as reflected in the fossil records of speech, partly the discovery and illustration of the laws which govern the shifting and decay of sounds and the modifications of sense."

The whole subject of phonetics is of course treated in a masterly manner, and well illustrated with diagrams and useful tables of Lautverschiebung as applicable to the Semitic, Bantu, Finno-Tataric, and Aryan families. The last, especially, is very full, including the Oscan and Umbrian, the Old Welsh and Gaulish, besides those usually given. It need scarcely be added that this, like all other branches, is brought well up to date, a good instance of which is afforded by the reference to the use already made of the phonograph in the scientific treatment of phonetics. Most readers will here learn, probably for the first time, the curious fact that "all sounds may be reproduced backwards by simply beginning with the last forms indented on the tin-foil: *sociability*, for example, becoming *ytibilaishos*. Diphthongs and double consonants may be reversed with equal clearness and precision, so that *bite*, which the phonograph pronounces *bâ-eet*, becomes *tee-âb*. In this way we have learnt that the *ch* of *cheque* is really a double letter, the reversed pronunciation of the word being *kesht*" (i. 335).

The question of mixed languages, that is, mixed in their structure, claims a good deal of attention, and is handled with considerable reserve. But the important truth is loudly proclaimed that the "physiological races of the modern world are far more mixed than the languages they speak; the physiologist has much more difficulty in distinguishing his races than has the glottologist in distinguishing his families of speech" (i. 366). This is perhaps as far as it is safe to go at present, and is sufficient for practical purposes. It points out that it is in the nature of ethnical groups to mix, and of linguistic groups to keep aloof, thus vindicating for language its rightful position in anthropological studies. It is not always or necessarily a test of race, but it is often an indispensable collateral agent of research, becomes under special circumstances, and with all due precaution, a final court of appeal, and in many cases bears witness to the presence of racial elements which would not otherwise be suspected. Its development also is extremely slow, slower even under certain conditions than that of physical types themselves, as shown, for instance, in the case of the Osmanli, Magyars, and many Finnish and Turkoman tribes, all of whom continue to speak purely agglutinating Finno-Tataric tongues, although through intermixture they have been largely assimilated to the Caucasian ethnical type.

The chapter on Roots (vol. ii.) is accompanied by a table of all known languages, for the classification of which Fr. Müller seems mainly responsible. The appended references to authorities will be found extremely useful, but the classification itself is defective in many respects, and calls for revision in future editions. Sonrhay and Haussa, for instance, ought not to be grouped together, nor have Wakuafi (read Ki-Kwafi) and Masai anything in common with the Nuba and Fulah groups. It is not clear why Berber any more than Egyptian (both Hamitic) should be described as sub-Semitic; but it is still more startling to find Brahui amongst the neo-Sanskritic tongues in company with Siah-Pôsh, which latter would appear to belong rather to the Galcha or pre-Sanskritic of the Eastern Turkestan Highlands, and which is unaccountably excluded altogether from the table. Etruscan, in spite of Corssen, is grouped apart as agglutinating, though there are many good authorities for this view. But Horpa is not a Tibeto-Burman isolating tongue, nor are Lolo and Mautse properly linguistic terms, but rather collective Chinese names of hill-tribes, mostly probably of Caucasian stock and untoned speech. The "Mon-Annam" family has no existence, the Mon or Talain having little to do with the Annam, and nothing at all with Kambojan, which belongs to a totally different connection. The Miztec, Matlalzinca, Totonac, and other Mexican tongues are described as isolating, all being polysynthetic, some, such as the Miztec, in the very highest degree with "bunch-words" of fifteen and even seventeen syllables.

The second volume is largely occupied with some of the principal linguistic families typical of the several orders of speech, followed by concluding chapters on Comparative Mythology and the Origin of Language, all handled in a masterly manner, extremely suggestive even when somewhat heterodox, and accompanied by much incidental matter of great value and interest. The statement (p. 324) that "the characteristics of race were fixed before the invention of speech" is one of those astonishing paradoxes which seem inseparable from original thought, but which remain none the less paradoxes. It is scarcely conceivable that the yellow, black, fair, and other fundamental types of mankind should have become slowly differentiated before man had acquired the faculty of speech, that is, the very faculty by which the human is distinguished from all other species, and that the art was then "invented" in various independent centres. But though it cannot be argued on this ground that "the idioms of mankind have had many independent starting-points" (p. 323), few will probably question the conclusion that linguistic science "can throw no light on the ethnological problem of the original unity or diversity of the human race" (p. 324). Such questions are truly "the task of the ethnologist, not of the student of language" (*ib.*) And even should the hope have to be finally abandoned of ultimately establishing the original unity of human speech, no argument could thence be deduced in favour of the original diversity of the human species. Dispersions of babbling tribes, whether originally one or not, probably took place at various stages in the evolution of human speech, or at times while it was still in process of formation, or when little more than the faculty existed, so that it must needs have afterwards developed into types no longer reducible to one hypothetical primæval type. This hypothetical type becomes daily more shadowy, continually retreating to the background of an inconceivably remote past, according as the astonishing complexity and diversity of articulate speech is revealed to the earnest student of

language. But it seems obvious that this diversity and complexity must have been evolved in the natural course, whether starting from one or many original centres.

At p. 163 a view is taken of the Aryan suffixes which many will be inclined to regard as a retrogressive step rather than an advance in linguistic studies. "We must rid ourselves of the notion that suffixes were ever independent words like our 'if' or 'in'; so far back as our knowledge of Aryan speech extends they possessed no existence apart from the words to which they belonged, and which, again, only existed as words in so far as they possessed these suffixes. Suffixes became flexions through the help of analogy." The point would involve too much technical matter to be here adequately discussed, but it may be remarked that our knowledge of Aryan speech is as of yesterday compared with the many ages it must have taken to reach the highly-inflected state presented by the oldest known members of the family. If in a brief thousand years or thereabouts the Latin ablative *mente* had time to become a Romance adverbial suffix, the verb *habeo* a verbal ending, and the adverb *inde* a pronoun with a genitival force, surely there was ample time in the ten, twenty, or fifty thousand years of the early lifetime of the organic Aryan speech for hundreds of independent words to pass from one part of speech to another, from the noun or verb to the particle, and thence to the relational suffix. And if "suffixes became flections through the help of analogy," being hitherto "meaningless terminations" (*ib.*), it may be asked through the help of what analogy? At all events, the internal vowel change here taken as their pattern does not meet the case, for, if properly considered, all such internal vowel change must itself be regarded as primarily due to the influence of reduplication and flection acting on the body of the word, and gradually becoming absorbed, often leaving no trace of its former presence beyond the very vowel change in question. Such seems undoubtedly to be the history of the strong Teutonic conjugation and of such Teutonic plurals as seem now to be effected by mere internal modification, just as we know that it is the history of such past tenses in Latin as *ēgi, fēci*. Two things it seems impossible to admit—the development or invention of "meaningless terminations," that is, meaningless *ab initio*, and internal vowel change with flectional force, produced, as it were, by spontaneous effort independently of outward influence, the influence either of reduplication or of pre- or postfixes reacting on the theme.

The chapter on Comparative Mythology, as expounded in the light of comparative philology, is thoroughly satisfactory, and will be read with pleasure even by those unfamiliar with the technicalities of the subject. In the last chapter, also, on the Origin of Language and collateral subjects, much excellent advice is given touching spelling reform, the pronunciation of the classical tongues, the application of sound linguistic principles to the teaching of languages, and many other points of a more practical nature.

There is an excellent analytical index supplied by Mr. W. G. Hird, but it does not dispense with the necessity of a full alphabetical index, which is urgently needed in a work overflowing with matter of the most varied description, and which it may be hoped will be supplied in future editions. Some oversights and casual slips in minor points should then also be rectified, and with that view a few of the more important may here be noted. The *ve* in the Italian compound *portandovelo* (ii. 210) is derived from the Latin adverb *ibi*, used pronominally instead of from the pronoun *vobis*. The particle *vi, ve* often, of course, represents *ibi*, as in the sentence *io v'era* (lit. *ego ibi eram*); but it equally represents the pronoun, as in the sentence *io vi dico* (lit. *ego vobis dico*), and obviously in the compound in question. The Nogairs (properly Nogais) are described (ii. 199) as "Russian Cossacks" instead of Tatars. The Nogais are of Tûrki stock, whereas all the Cossacks are of Slav stock, either Great Russians (Don Valley, Cis-Caucasia, &c.), or Little Russians (Ukrania). The Cossacks are often spoken of as Tatars by careless writers, confounding them with the *Cassaks*, who, being Kirghizes, are true Tatars. It seems scarcely accurate to say that in the Greek and Latin sentences τύπτει and *amat* "the subject is not expressed" (ii. 329), seeing that ει (for ετι) and the *t* of *amat* are pronominal, though so old that they do not distinguish the gender of the subject referred to, and may possibly have originally been *objective* forms. The statement (i. 417) that "in Hindustani the genitive takes the marks of gender according to the words to which it refers," is apt to mislead the unwary, who might conclude from this that the Hindustani noun had cases, whereas there is nothing but a general oblique form followed by postpositions. One of these postpositions (*kā* = of) follows the gender of the noun of reference (*larkē-kā, larkē-kī* according to circumstances), but the noun remains unchanged. There is another reference (p. 423) to a point of Hindustani grammar, which as worded is unintelligible. The place of the definite article is not supplied "by a dative with the suffix *-ko*," for there are no datives, but by the postposition *ko*, which, though usually giving a dative force, often idiomatically emphasises the objective noun and thus does duty as a sort of definite article. The reference to Voltaire (i. 60) should be emended by shifting the places of the words "consonants" and "vowels." No one who has ever heard a native of Northern India speak any of the current neo-Sanskritic tongues will hesitate to transcribe the sonant explosives with the rough breathing (*gha, dha, bha*) by the side of *kha, tha, pha*, though the point is treated as doubtful (i. 281). The *h* in such words as *ghora, bhā,ī, dhōbi* is heard quite as distinctly as it is in the English word *mad-house*. Lastly, such terms as "Turanian" (i. 325), "Alfurian," and even Malayo-Polynesian might well be dispensed with in future editions of a work, which as it stands reflects lasting credit on English scholarship, and which all will accordingly be anxious to see rendered even in small details as perfect as possible.

A. H. KEANE

STATICS

Treatise on Statics. By George Minchin, M.A. Second Edition. (Clarendon Press Series.)

SINCE the publication of Thomson and Tait's "Natural Philosophy," thirteen years ago, an important change in the treatment of the theory of dynamics has been making rapid progress. Previous to that time it was the almost universal practice to follow the French writers and to find a basis for the theory of the equilibrium of forces

independent of any consideration of motion. Force was often defined to be that which caused or tended to cause motion; but the theory of the combination and resolution of forces was founded on certain assumed axioms about the properties of forces without further reference to the effect by which force was described. The proof of the parallelogram of forces was to most beginners such a formidable *pons asinorum* that the broad conception that velocities, accelerations, and forces acting at given points were all fully represented by vectors, and that each could be added just in the same way as the vectors which represented them, was not soon grasped by the mind. Consideration of the fundamental principles of dynamics and of the philosophic position of the first law of motion, which at the same time defines the measure of time and states a law of nature, was avoided, and the theory of the motion of matter became a development of the equations of statics.

Thomson and Tait returned to the order of Newton and abolished artifices from the foundations of the science of dynamics. The influence of Thomson and Tait's "Natural Philosophy" on the volume before us is apparent in the first chapter. The proofs of the parallelogram of forces by Duchayla and Duhammel are conspicuously absent, and the fundamental proposition of statics is deduced quite naturally from consideration of the parallelogram of velocities. When it is once admitted that statics should rest on Newton's laws of motion, the appropriateness of a separate treatise on the subject, to include electrostatics and elasticity, becomes questionable. Why should dynamics be divided and a separate treatise be written on that portion from which it is possible to exclude the idea of mass? A book on the analysis of systems of forces or "wrenches" deals with a natural group of propositions, so does a book on attractions, on electrostatics, or the relations of stresses and strains. But we cannot see that it is natural to group those subjects together with the view, as it would appear, that the student should make himself acquainted with them before mastering the dynamics of a particle. Indeed, however we may admire each chapter of Prof. Minchin's work, we cannot help regretting that he has limited his subject-matter by the title of the volume.

At the end of each chapter is an abundant selection of examples—a very necessary part of an educational work on any department of mathematics. It would have been well that amongst these should have been found a larger proportion of examples demanding a numerical answer; the best students show a liability to failure in rapidly dealing with dynamical questions when concrete numbers take the place of the more familiar symbols.

It is not often that a graduate of Dublin University omits to set forth in its proper place the work of a Dublin professor. Any one would have looked with considerable confidence in Chapter X. of Minchin's "Statics" for some account of Ball's theory of screws as a sequel to Poinsot's central axis, but he would be disappointed. As that theory is very instructive as well as exceedingly elegant, the omission is a loss to the student.

Chapter IX. is devoted to friction, and ends with four articles on the friction of a pivot, based on the assumption that the pressure between pivot and footstep is uniform over the surfaces in contact; and in Art. 134 the equation of the tractory is found by a further condition that the vertical wear shall be constant. As a fact, when a pivot has been at work for some time the vertical wear becomes of necessity constant, and thence may be deduced the normal pressure at any point which will not be constant unless the form of the pivot be the tractory. As an illustration we propose the following to our readers: A conical footstep is to bear a maximum load with a minimum frictional moment; show that it should have a hole in the middle one-third the diameter of the footstep. A similar consideration may be applied to ascertain the distribution of pressure between a horizontal shaft and an ordinary bearing.

The book ends with a chapter on stresses and strains and their relation to each other. The examples appended to this chapter will be found most useful to the student; so far as we know he will not find elsewhere such facilities for testing his skill in this department of dynamics. Although we do not think it desirable that the departments of the science of dynamics should be classified for teaching purposes into statics and kinetics so completely as the present volume implies, we can heartily recommend each several chapter for the subject on which it treats, and we hope that Prof. Minchin will produce a work dealing with kinetics, and that when a fresh edition of both is demanded he will weld them into a single treatise on dynamics.

AUSTRALIAN ORCHIDS

Australian Orchids. By R. O. Fitzgerald, F.L.S. Part V. (Sydney, N.S.W.)

THE part of this beautiful and instructive work which has just reached us contains ten plates, illustrations of sixteen species belonging to the genera Prasophyllum, Thelymitra, Sarcochilus, Dendrobium, Pterostylis, Cleisostoma, and Bolbophyllum, all full of analyses, displaying in a very satisfactory manner the forms, disposition, and, in many instances, the development of the reproductive organs; whilst the letterpress is as full as is that of previous parts, of curious and instructive observations on the habits of the species and their modes of fertilisation. Whether, in point of scientific importance, or fulness of illustration, there are few works upon the Orchideæ to compare with this, certainly none at all comparable to it has ever been attempted in a colony. Its only rivals are the magnificent orchideous plates in Blume's "Rumphia," and in his still more beautiful "Orchideæ of the Indian Archipelago." On the other hand, in respect of descriptive matter the works of these two authors widely differ. Blume had to deal with a host of previously unanalysed and unnamed generic and specific forms, which he classified and described in a truly masterly manner, and his works are hence almost purely systematic. The materials for the "Australian Orchids" had been for the most part classified by Brown in the "Prodromus Floræ Novæ Hollandiæ," with a skill equal to that subsequently displayed by Blume in respect of the Indian ones, and Mr. Fitzgerald has therefore rightly devoted his descriptive matter chiefly to the "life-history" of the species. As a specimen of this we may quote his observations on *Prasophyllum fimbriatum*:—

"This little flower presents another of the anomalies

frequent in the family. So constantly does the labellum appear to act as a resting-place for insects, that in trying to trace the probable manner in which they fertilise a species, you naturally look upon it as the platform of the operator; but in this case, should a tiny insect alight upon one of the lips which hang trembling from the flowers, it would meet with a projection resembling the column and in the same position usually occupied by it, but without anther or stigma, being in fact nothing more than the hinge from which the fringed lip depends. This baffling is caused by the flowers being inverted, and the dropping of the labellum in front of them. Such modifications as this are useful in checking the natural tendency to assume that a certain part of a flower is designed to act in a certain way simply because through a long series we find it performing that function, and to show us how a slight change may alter all the results. Here the labellum bars access from the ordinary direction; the lower sepal incloses the column from below; the petals and wings of the column intercept access from the sides, and a prolongation of the anther obstructs it from the end; so that a very small space is left open beneath the labellum in what would appear to be the least likely place for an insect to approach, though from the conformation of the column the intervention of insects seems to be a necessity. After a very careful examination, I came to the conclusion that the most probable method in which this interesting little orchid becomes impregnated is by a very minute insect alighting on the under surface of the labellum and following it up into the flower, the lip giving way to its pressure upwards (by being lifted on the hinge) should the visitor be slightly too large. Would not the chances of the reproduction of this species be improved by the removal of the labellum? This, then, is another instance of a part of a flower, generally of importance, becoming of very doubtful advantage, if not actually detrimental."

Hitherto Mr. Fitzgerald's studies have been confined to the orchids of Eastern Australia, but it is most earnestly to be desired that they will be extended to the southern and western species, as indeed the title of his work implies will be the case.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Ice-Crystals

SINCE the publication of the Duke of Argyll's first communication on "Ice-Crystals" (NATURE, vol. xxi. p. 274), I have been expecting that some of the physicists who have noticed similar phenomena would have looked up the *literature* of the subject.

About thirty years ago I made this class of phenomena the subject of a somewhat careful investigation, and published the results of my researches in the *Proc. Am. Assoc. for Adv. of Sci.*, third meeting, March, 1850, vol. iii. pp. 20-34; also in the *Phil. Mag.*, 3rd series, vol. xxxvi. pp. 329-342, May, 1850. The *former article* is illustrated by several engravings representing the appearances presented by the "exudation of ice" from the foot-stalks of the *Pluchea*. I think that my investigations show that the phenomenon in *plants* is purely *physical*, having no connection with the *vitality* of the stems; and that it is due to the *same cause* as the "protrusion of icy columns" from the ground in frosty weather.

In relation to the *explanation* of the phenomena, I have nothing to add to that given in the above-mentioned paper, except in relation to *two points*, viz. (1), that I did not sufficiently *emphasise* the importance of the fact that the water contained in the *capillary* tubes in the upper stratum of earth is cooled many degrees *below* the freezing temperature; and (2) that, consequently, the congelation would necessarily take place *paroxysmally*.

JOHN LE CONTE

Berkeley, California, April 27

Anchor-Ice

MY remarks on anchor-ice, published in NATURE, vol. xxi. p. 538, have called forth several letters to myself, in addition to the articles on this subject by Mr. Allan Macdougall and C. F. C. respectively, which have a place in vol. xxi. p. 612 and vol. xxii. p. 31 of your journal. I am happy to find that C. F. C. agrees generally with my views, but I regret to have to differ from him when he says that "the original (ice) crystals, if not *heavier than water*, are at least as heavy." Were this supposition true, anchor-ice might as readily form in one part of a stream as in another, and would not require the conditions which I believe to be necessary. These minute crystals have never been seen by me "distributed" pretty evenly throughout the body of water at rest, nor even where there was a smooth, slow, steady current, which would be the case if the specific gravity of the crystal and water were alike.

C. F. C. is right in saying that this ice resembles manufactured "water ices"; it is never, as far as I know, transparent. It also looks like salt-water-ice.

Mr. Macdougall tells us of anchor-ice in Georgian Bay. This at first sight would appear to be incompatible or at variance with my belief in the necessity of a "comparatively swifter current" being essential for this formation, but to those who are familiar with the large lakes of America, the apparent contradiction seems not difficult of explanation.

At Great Bear Lake inexplicable currents of several miles an hour, sometimes running against the wind, are found in many of the narrow and shallow channels separating islands from the shore, making agitation sufficient to disturb the equilibrium of the floating ice-crystals and surface cold water. The same condition of things doubtless obtains in the Georgian Bay, which is the most easterly portion of the extensive and irregularly-shaped Lake Huron.

One remark of Mr. Macdougall's, to the effect that "the anchor-ice in the great northern lakes *floats* at a considerable depth under the surface of the water, and that it seemed to be floating at various depths in water fourteen feet deep," is curious. One way of accounting for this peculiarity may be that when the air becomes detached from the bottom, it not improbably brings up with it stones or gravel; soon afterwards a part of the ice gets separated, thus diminishing the floating-power, until the specific gravity of the compound mass exactly equals that of water, in which condition it might, of course, be found "swimming" at any depth below the surface.

Mr. Macdougall asks, "Does the (anchor) ice form by action of the intense cold of the ground (meaning, I presume, the bottom of the lake or stream), favouring the formation of rasee?"

I do not think that as a rule the coldness of the ground has anything to do with this formation, except in so far as this coldness of the ground, *i.e.*, the stony bottom, is caused by contact with the ice-cold water and ice-crystals, as already mentioned. "Intense coldness" of the ground at the bottom of the middle of a stream can scarcely be caused by abstraction of caloric, through its connection with the supposed colder land on shore, which is usually covered and protected by snow from cold in early winter; also, were this the cause, or one of the causes, the part of the river nearest the shore would first show anchor-ice, which is not the case.

At Repulse Bay flooding of some of the rapids of North Pole River took place when the ice was forming. This we know could not be caused by a greater flow of water, as the lakes supplying the river and all the rivulets running into them were already firmly ice-bound.

These overflows were caused by barriers of anchor-ice, which dammed the water up to the height of two or three feet, until the pressure became so great as to force a passage through the soft but tenacious mass, the portion of which that remained unbroken being now, by the running off of the water, brought into contact with the cold air, soon became frozen hard and solid.

"Sarsens"

I SUPPOSE it is in the order of things that utility should be a prime consideration, but still one cannot but regret the wholesale destruction which is overtaking the picturesque stones which have given its name to the "Valley of Grey Wethers," near Marlborough.

This destruction has been going on for some years, as is witnessed by the cottages in the neighbourhood built of "sarsen," but has of late been vastly increased by the demand for this strong stone for the bridges on the railway now making between Swindon and Marlborough. Nearly all the large blocks have indeed already disappeared.

So far no attack has been made on the fine cromlech of the "Devil's Den," which lies at the foot of the valley. It has had a narrow escape before, for a weather-beaten shepherd told me some years back that he "minded" how when he was a boy the farmer there got all the horses and oxen and tackle he could in the parish and laid on to the capstone, and "they drawed 'un and drawed 'un, but *it warn't to be moved*."

The geological interest in these rugged stones is considerable. They are found, more or less, all over the chalk range, but always as scattered or isolated blocks. The temple at Avebury was constructed of monoliths of this stone, so is most part of Stonehenge. The cromlechs of "Kit's Cotty" and "Wayland Smith's Cave" are formed of it, and its curious mode of weathering is well shown by the "blowing stone" under Uffington Camp. There is hardly a village amongst the chalk hills in which a mass of this rugged stone may not be seen, but nowhere is it found in anything like the abundance which has characterised the "Valley of Grey Wethers."

It is, I believe, the generally-accepted view that these "sarsens" are the indurated remains of a tertiary stratum of sand with which the chalk was once overlaid. Perhaps some of your readers can inform me where these stones can be seen in their native sand. The circumstance of the fracture of some of the "grey wethers" near Marlborough disclosing imbedded in them what look to me like chalk flints possibly points to an earlier origin for them. A. G. RENSHAW

May 19

AN ENTOMOSTRACON LIVING IN TREE-TOPS

IT is not to be wondered at that the moist and shady hiding-places between the leaves of the Bromeliads, filled as they are by food of various descriptions, should be occupied by all sorts of animals, and that some of these should have chosen them as their favourite abodes and should have exclusively deposited their eggs in them. And indeed, according to Fritz Müller's friend, Friedenreich, almost all the coleoptera peculiar to the Bromeliads have been for the last thirty years found by him exclusively in such places, and the same is probably true of the larvæ of very many species of insects, and for the tadpoles of the tree-frogs, which undergo their metamorphoses therein.

But for all this it is, as Fritz Müller, writing from Itajahy, November, 1879, says, a very astonishing thing that there should be found living among the aquatic animals in the tops of the woods a little crustacean whose relations one is accustomed to find among the sea-weeds. It is about one millimetre long, and is of the family of the Cytheridæ.

Of the two cosmopolitan genera, each rich in species, Cypris and Cythere, into which the untiring investigator of the salt and fresh waters of Denmark, Otto Friedrich Müller, divided the bivalved crustacea, those of the first (Cypris) live almost entirely in fresh, and those of the second (Cythere) almost entirely in salt, water. Only a very few isolated exceptions to this rule have as yet come to light, and in the Brazils Fritz Müller only knows Cythere as having marine species, while those of Cypris are from fresh water; and never would he have expected to meet with, on the trees of his wood at Itajahy, an old Baltic acquaintance which he erewhile had collected when wading bare-footed with Max Schultze in Greiswalder Bay. At the first glance he did not recognise the Cythere of the Bromeliads as a relation of its recent marine cousins, because it differed a good deal in the shape of its bivalved shell from all known species of Cythere, and even from all known Entomostraca. These generally possess laterally-compressed valves, which are broader than they are long, and are commonly bean-shaped. In the Bromeliad-lodger the length of the valves is a good deal more than the breadth, and, in addition, the ventral surface is flattened, and has a longitudinal furrow, reminding one of a coffee-bean. In consequence of this, when this new form is out of the water, instead of falling on its side as the others would do, it falls upon its back, or upon its ventral surface. This is probably an adaptation to its place of abode. In the sea the species of Cythere climb up on the narrow filaments of the algæ; and in the Bromeliads they must move about on the flat surfaces of adjacent leaves.

While no recent entomostracon was known to Fritz Müller which this new form resembles, he was at once reminded of a species (*Elpe pinguis*) which occurs as one of the oldest fossil Cytheridæ, and which Barrande described from the Silurian strata of Bohemia. This the Bromeliad form very closely resembles, but it is just five times as small. Fritz Müller describes this new form as *Elpidium bromeliarum*, for though it possesses no very marked peculiarities in its feet, still it does not fit into even any of the genera into which the old genus Cythere has been of late subdivided.

Elpidium Bromeliarum, Fr. Müller. 1, dorsal aspect; 2, ventral aspect; 3, side view, right valve removed; 4, anterior antenna; 5, 6, posterior antenna of male and of female; 7, mandible; 8, maxilla; 9, 10, 11, feet, of 1st, 2nd, and 3rd pairs; 12, last body segments; 13 and 14, egg and young, from the parent valves; 15, *Elpe pinguis*, Barr. Magnified 1 to 3 = 10 : 1; 4 to 12 = 71 : 1; and 13 and 14 = 36 : 1.

Everywhere that Fritz Müller has looked for this new form, from the sea-side to some hundred kilometres into the interior, he has found it common in the tree-frequenting Bromeliads of the primæval woods. As it cannot, like some other of the animals inhabiting such places, wander from tree to tree, or even from one plant of Bromelia to another, its distribution must be affected by beetles (Agabus, Laccophilus, Hister, &c.), or some other of the Bromelia investing forms. The young Elpidia, when they leave their mother, are only 0·2 mill. long, and doubtless they cling to some of the flying insects, and so are transported. As, however, the colonisation of the Bromeliads is thus seemingly entirely left to chance, it

is the more astonishing that these little crustacea are found in almost every Bromeliad.

It cannot but sometimes happen that a few specimens must be washed away into other waters, as on the contrary, one may sometimes meet with a stray entrapped Cyclops that has slipped into the Bromeliads. Yet Fritz Müller has hitherto searched in vain for Elpidium in running waters, which produce, among other species, Cypris, Cyclops, Canthocamptus, Chydorus, Alona, Camptocercus, Pasithea, Moina, Ceriodaphnia, Simocephalus, &c. It seems not to flourish outside the Bromeliads.

[Translated from *Kosmos*, February, 1880. *Elpidium* comes somewhat near to *Elpidia*, Theel.—E. P. W.]

ON THE PHYSICAL ASPECTS OF THE VORTEX-ATOM THEORY

In all attempts to arrive at a satisfactory conception of the ultimate constitution of matter, the grand difficulty has hitherto been to reconcile the proved indestructibility of the atom with its capacity for executing vibrations, as demonstrated by the spectroscope. The ancients, by assuming the atom to be *infinitely hard*, attempted in this way to get over the difficulty of indestructibility (or indivisibility), but thereby debarred all means of conceiving the "*elasticity*" of atoms, or their known powers of taking up vibrations of different periods.

When we consider the immense difficulty that there must have been in conceiving how an atom could be elastic (*i.e.*, how its parts could be capable of free motion) and yet its parts be incapable of separation from each other, we may well excuse the attempt to explain indestructibility by the assumption of the quality of *infinite hardness*, unsatisfactory though it might be.

It is evident that if we are to renounce all idea of occult qualities of "elasticity," hardness, indivisibility, &c., and purpose to explain the facts without recourse to postulates, we must assume the material substance of which our atoms are to be formed, to be itself entirely without any positive qualities, *i.e.*, to be without elasticity, hardness, rigidity, &c., and therefore to be freely penetrable in all parts, or perfectly passive and inert. This is the perfect liquid of the vortex-atom theory. There may be some who would say that it is difficult to conceive of such a liquid. On the contrary, we venture to be able to prove that such a liquid *always is conceived of* whenever a liquid is thought of. Thus, does any one in conceiving of a liquid (water, for instance), regard the liquid as consisting of solid (*i.e.*, more or less rigid) portions of matter sliding over each other [as we might conceive solid masses sliding past or through each other on a magnified scale]; and yet this is truly what the liquid (composed of molecules) is in the actual fact. In short it is not a "*liquid*" at all. Yet we conceive of it as *liquid, i.e.*, freely penetrable in all parts. We therefore contend that a perfect liquid (or true liquid) is what is *always* conceived of, and therefore that there can be no difficulty in regard to the conception of the true liquid that forms the basis of the vortex-atom theory.

In the next place, it is an obvious condition to any consistent conception of matter that matter must possess *extension*,[1] or occupy space, *i.e.*, so that two portions of our liquid cannot occupy the same space at the same time. If, therefore, the liquid fills all space, it must be incompressible. This is, therefore, not an arbitrary postulate.

The next question naturally suggesting itself would be, how are portions of such a liquid to attain the properties that we recognise in atoms? We venture to think it will be conceded as evident that the only *conceivable* way (if it be admitted that the result is attainable at all) is through *motion* [for this is the only conceivable way in which the liquid can be affected]. The further inquiry would therefore be, what would be the *character* of this motion? Now, in order to fulfil the condition that the atom itself can be brought to rest without losing its properties as an atom, it is evident that the motion of the material forming it must take place in such a way that the atom can remain in one spot, or be to our senses at rest, *i.e.*, the material of the atom, although in motion, must not deviate from one spot. We ask if there is any other *conceivable* form of motion than *rotary* motion that would fulfil this condition? Hence the necessity for looking to *rotary* motion as the basis of the properties of the atom. In the next place a portion of material in rotation must rotate about an *axis*. If the ends of this axis were exposed, we should have two points *at rest*, which would forfeit the condition of *motion* being the essential basis of the external qualities of our atom. The question is, therefore, how is a portion of material to be in rotation about an axis, and yet not expose the ends of the axis? The only *conceivable* answer (as we think will be admitted) is that the rotating portion of material must have the form of a closed ring, or complete circuit, so that the axis has no ends. We therefore think it may be said beforehand that conceding that the problem of the atom can be solved at all (or if it be conceded that a fact can exist solely in virtue of the explanation that underlies it) then the problem could only *conceivably* be solved under the fundamental conditions above developed, *i.e.*, under the condition of a portion of material (having no positive properties in itself) *rotating* in the form of a *closed circuit*.

This (as is well known) is what has been found to satisfy the conditions for the atom by the application of mathematical analysis (without, apparently, that object having been in view at all), and in a manner the most remarkable in its completeness. It appears possible, in view of the above considerations, that a profound and competent thinker who had devoted himself to the subject might have arrived, even before the mathematical analysis had been applied, at the *sole conceivable* physical conditions that in principle could satisfy the problem of the atom (admitting the *existence* of the solution); but the mathematical analysis can of course alone make the fact of the solution apparent to us. It is related in the article on "The Atomic Theory of Lucretius" (*North British Review*, March, 1868) that Hobbes had arrived at the fundamental idea that the *rotation* of a portion of material must be the basis to the solution of the problem of the "elasticity" of the atom, without having applied any mathematics.

The difficulty of the mathematical side of the vortex-atom theory is curiously contrasted with the simplicity of the physical side of the theory. If we suppose a cylindrical bar of india-rubber to be rotated about its longitudinal axis, and the bar (still rotating) to be bent round into a ring shape and the ends joined (the rotation of the material of the ring being always continued), then this may serve to illustrate in a simple way the motion of the material forming the vortex-atom. It is here apparent that the material of the india-rubber ring (in our illustrative case) may be in rapid motion while the ring itself preserves a fixed position in space. It would seem to be a pity if a spurious mystery should be allowed to envelope this subject, which is unworthy of it, in view of the simplicity of its physical basis. No one doubts the difficulties that had to be surmounted on the mathematical side of the theory, but there is all the more reason on that account that the extreme simplicity of the physical side of the theory should be duly appreciated, and unnecessary obstacles not be thrown in the way of its adoption. The tendency to invest physical subjects with a halo of the occult [possibly partly attributable to the unfortunate introduction into physical science of the spiritualistic conception of "*force*"—in the sense of an action across space without the intervention of matter] has probably done more to hinder progress than any real difficulties.

[1] The quality of extension may even be regarded as included in the definition of matter.

We shall simply state the facts of the mathematical analysis here, our business being more particularly with the physical side of the theory. First it is shown by incontrovertible mathematical proof that a portion of material having the motion above described possesses all the qualities of a *solid*. It is at the same time "*elastic*," or capable of changes of form when acted on through impact by other atoms—always tending to return to its symmetrical form when removed from constraint. It is, moreover, proved to be competent to execute vibrations of definite periods which it is the function of the spectroscope to measure. The atom thus constituted is demonstrated to be incapable of being divided or severed by the collisions of other similar atoms against it, and *since this is the sole means of acting upon it*, the long-standing riddle of indestructibility is thus simply solved, without the necessity for any postulate of *infinite* hardness. As the degree of hardness merely depends on the velocity of rotation of the material, it follows that the vortex-atom may possess any degree of hardness. Indeed, if we imagine the atom to be magnified up to visible scale, it might be conceived to be harder or more rigid than a ring of steel of the same dimensions, since the hardness of steel is limited by the resistance of the component atoms to displacement.

The centrifugal tendency of the rotating material of the vortex-atom is controlled by the exterior incompressible liquid, and as there is no friction [there being no ultimate solid parts in the rotating liquid to "catch" against the inclosing fluid walls], the rotating portion therefore glides smoothly over the incompressible liquid that surrounds it like a pipe. Indeed, if we leave out of our conceptions the portion of rotating liquid, then the surrounding liquid actually forms a complete pipe in the form of a closed ring. If the liquid in the pipe were to fly out, a temporary void would be formed in it, which is impossible in a liquid that already occupies all space. An idea of the resistance of such a rotating portion of material to bending may be got by attempting to deflect a gyroscope or spinning-top.

In the old idea of *infinitely* hard atoms there were difficulties in forming a satisfactory conception of what took place at the collision of two such atoms or how the rebound could effect itself (consistently with the conservation of energy). The following difficulty may also be mentioned :—Since two such atoms are supposed to be absolutely hard or unyielding, the area of contact at the collision would necessarily be merely a mathematical point. Now the intensity of a given pressure on a surface is inversely as its area ; and accordingly, since the area is here a mathematical point (or infinitely small), the pressure attendant on the collision of the two atoms would require to be *infinitely* great. It may be a fair question how even an *infinitely* hard atom is to withstand the disintegrating influence of an *infinite* pressure.[1]

In the case of the vortex-atoms they yield somewhat at collision (without change of volume, of course), whereby the encounter takes place over a surface (not a point) ; and they rebound in virtue of their elasticity, due to the motion of the material forming them.[2]

There would seem to be a view to a certain extent prevalent that the vortex-atom theory essentially alters the basis of the old-established ideas of solid indestructible atoms surrounded by space in which they can freely move, to which so many have accustomed their conceptions, and worked upon to the successful discovery of new facts, and which ideas, therefore, they might be reluctant to abandon. This step, however, is not required at all. The main purpose of the vortex-atom theory is to explain the "*elasticity*" of atoms, retaining substantially everything else appertaining to the old atomic theories, merely removing the unsatisfactory postulate of *infinite* hardness. For since the perfect liquid (outside the portions of it that form the atoms) opposes no resistance whatever to the passage of the atoms through it, or it is impossible to act on the exterior liquid, it is therefore in this respect as if a void existed outside the atoms. It is desirable, however, to note that the vortex-atom theory involves essentially the *existence* of the liquid outside the atoms, which performs important functions, but since this exterior liquid is proved to be incapable of appealing to our senses in any way, it therefore *in that respect* may be said to play the part of a void. The exterior liquid of the vortex-atom theory corresponds to the void space of the theory of Lucretius. With the above qualification, therefore, it may be allowable, when we are not specially dealing with the problem of the constitution of the atom itself, to leave out of our conceptions the presence of the exterior liquid: that which we call "matter" being the atoms, and not the exterior liquid. In all practical problems of physics, therefore (apart from the problem of the constitution of the atom), we may properly regard the atoms simply as *elastic* indestructible solids moving freely in space. Moreover, since the motion of rotation of the material of the atom is incapable of transference, and cannot appeal to our senses, and this motion does not in any way alter the position of the atom in space [but it is exactly as if the atom *itself* were at rest] ; we can therefore, if we like, leave this rotatory motion out of our conceptions, merely keeping in view the result produced by the rotation, viz., the sharply-defined elastic indestructible solid thereby formed. The function of the modern theory is accordingly not to destroy the atomic theory of the ancients, but rather to support it, by explaining *how* such indestructible bodies can exist, without recourse to the unacceptable postulate of *infinite* hardness. This old theory of the atomic constitution of matter was really too firmly grounded on reason and observation, as that one should suppose that its very foundations could be shaken.

Broadly and generally, therefore, in practical problems of physics, the essential points to recognise are that atoms—or molecules—are elastic indestructible bodies, capable of rebounding from each other without loss of energy, and of executing vibrations of fixed periods. The existence of this *elasticity* is a fact so definitely proved by the spectroscope, which actually measures the *number* of vibrations executed per second by molecules, that it would become a question to *explain* this fact, even if the vortex-atom theory had not been proved to be capable of affording a complete explanation of it. Indeed, not only is the theory *capable* of doing this, but the vibrating capacity possessed by molecules is shown to be a *necessary* consequence of the theory, so that, therefore, the fact might even have been deduced *à priori*. Considering how enormously difficult it appeared to account for this fact at one time, or how impossible it seemed to reconcile the mobility of the parts of a molecule with the inseparability of these parts by the most energetic collisions, and how an explanation of this fact was at one time sought after, it would appear not too much to expect that those who hesitate to accept the explanation given by the vortex-atom theory, should endeavour to define for themselves wherein their grounds of objection lie. For if the explanation of a fact be admitted to be substantially complete, it would be at least unreasonable to look for more. The question might also suggest itself as a fitting one to any impartial inquirer, whether any other solution to the problem of the constitution of the atom is in principle *conceivable*, or whether [as in the case of many other physical problems, the constitution of the ether, for instance] but *one* solution is conceivable (or we have no choice at all). It cannot be said at least that the theory of vortex-atoms, or its physical side, is not *simple*, dealing

[1] The fact of two such infinitely hard atoms being stopped in an infinitely short space at collision [for there is by hypothesis no *gradual* yielding] would by itself entail an infinite pressure *in addition* to the infinite pressure due to touching at a mathematical point.

[2] The rebound of vortex-atoms may be illustrated (as is known) roughly by the rebound of two smoke-rings from each other, or by the rebound of vortex rings in an ordinary (imperfect) liquid.

as it does with the mere *rotation* of a portion of matter.[1] It is so far recognised that simplicity of the means to the end is a general characteristic of nature. No doubt there may be difficulties in the mathematical development of the subject; but if an atom be once proved to be elastic and indestructible, that fact surely goes very far to supply all we want for the practical applications of the theory. Of course there may be some refinements that may present great mathematical difficulties. For instance, Prof. Tait in his work, "Lectures on some Recent Advances in Physical Science," mentions a case where a vortex-ring is supposed to come into collision with another in such a way that the motion is not symmetrical in relation to the axis, and it is cited as an almost insurmountable difficulty to find what exactly takes place (in regard to particular vibrations or rotations developed, possibly). But one might ask, is it necessary to know this for practical problems of physics? We may know broadly that vibration or rotation is developed, and if so (apart from the abstract interest of the question), do we want to know precise quantitative details for practical purposes? It might for example be extremely difficult to determine mathematically the exact deformation or changes of form (vibrations, &c.) that a steel ring underwent when thrown against the hard surface of an anvil; but the practical question is, do we want to be acquainted with this for any ordinary problem that might occur, or in order to appreciate the general principles of impact, for instance? So in the case of vortex-atoms, no doubt many instances might be cited when it would be difficult to ascertain precise results, but the practical question is, Does this prevent our applying the theory to ordinary physical problems,[2] or to dynamical phenomena involving questions of principle? For possibly it may not be necessary to know the exact vibrations developed at a collision (for instance), provided we recognise the fundamental point that energy is conserved, and that the atoms can rebound from each other like perfectly elastic solids. It would be a pity if the mere *difficulty* of arriving at precise mathematical results of a refined character, should be mistaken by some for *mystery*, or it would be a thing to be regretted if there should be any tendency to throw a veil of the "occult" over what in its *physical basis* (at least) is very simple, this procedure only hindering progress and rendering a closed book what might be a most interesting branch of mechanics.

The investigations regarding the perfect liquid have already (as is known) thrown some important light on the important practical question of the resistance of ships. Mr. Froude has especially devoted himself to these inquiries. The old idea that a ship (or more correctly a totally immersed body, such as a fish) encountered a mysterious resistance in addition to the mere friction of the molecules of water on its sides, is now known to have been a pure delusion. If it were not for the fact that the water consisted of molecules or ultimate rigid parts which are caught and put in motion by the rough sides of the ship, there would be demonstrably no resistance at all. Hence the absence of resistance in a true liquid (which is not formed of ultimate rigid parts or molecules). If the molecules or ultimate rigid parts of which an ordinary "liquid" consists, were to be liquefied, a being immersed in it would (if conscious) imagine he was surrounded by empty space.

The late Prof. Clerk Maxwell in a review of the theory of vortex-atoms in the "Encyclopædia Britannica" for 1875, under the word "*Atom*," makes the following remark on the theory:—

"But the greatest recommendation of this theory from a philosophical point of view, is that its success in explaining phenomena does not depend on the ingenuity with which its contrivers 'save appearances' by introducing first one hypothetical force and then another. When the vortex-atom is once set in motion, all its properties are absolutely fixed and determined by the laws of motion of the primitive fluid, which are fully expressed in the fundamental equations. The disciple of Lucretius may cut and carve his solid atoms in the hope of getting them to combine into worlds; the follower of Boscovich may imagine new laws of force to meet the requirements of each new phenomenon; but he who dares to plant his feet in the path opened out by Helmholtz and Thomson has no such resources. His primitive fluid has no other properties than inertia, invariable density, and perfect mobility, and the method by which the motion of this fluid is to be traced is pure mathematical analysis. The difficulties of this method are enormous, but the glory of surmounting them would be unique" [p. 45].

Much misapprehension would seem to exist in regard to the physical side of the theory, especially in Germany,[1] where the mathematical investigations out of which it sprung, had their origin. Some appear to be unable to conceive how motion should take place in a material substance continuously filling space, losing sight of the fact that the liquid outside the atoms plays the part of a void (in so far as it cannot appeal to our senses)—or it is only the atoms that affect our perceptions. Others fail totally to appreciate the simplicity of the physical side of the theory, and seem to think it involves arbitrary postulates, whereas the main peculiarity of the theory is its freedom from positive assumptions, inasmuch as the theory evolves all the properties of matter out of the *motion* of a material substance, which without this motion has no positive qualities at all, and could not appeal to our senses. The fact seems to be overlooked that if we renounce the occult quality of *rigidity* in the atom, we have no other resource than a *liquid* (*i.e.*, a substance without rigidity). Much of the misunderstanding on the subject may no doubt be due to the scarcity of the literature relating to it, and the extreme brevity and absence of detail or attempt to assist the conceptions regarding the physical side of the theory. This want the author himself has much felt, and having been at considerable trouble to render clear his own conceptions as far as he could, he has thought that the result of this analysis might not perhaps be unacceptable in the form of a paper on the *physical aspects* of the theory.[2] For there are no doubt

[1] It would seem to be thought by some that the primary *ring* form of the vortex-atom involves something complicated in it. I venture to think that this is only one of those first impressions, which will disappear on reflecting on the subject. First, many facts strongly indicate that matter possesses a more or less *open* structure (or is highly porous). These ring-molecules would give matter an open structure. It would seem also independently probable that a molecule should have no more material in it than is essential to give it a certain amount of *extension*, or to make it occupy a certain range of space. Why should we suppose that waste or apparent superfluity of material in a molecule that a solid structure throughout would involve? Does not this violate one of the fundamental principles of large scale architecture, where superfluity of material is recognised as one of the worst faults, and mechanical principles are admittedly independent of scale? The *ring* shape for the atom is evidently the simplest elementary form to satisfy the condition for the maximum of *extension* combined with the minimum waste or expenditure of material. In view of these considerations, the ring-shape, the primary form required by the vortex-atom theory, may seem in itself independently probable. Indeed, it seems a remarkable fact that the main conditions inevitably led up to by this theory by a rigid mathematical process, are precisely those that independent observations support, (1) the *indestructibility* of the atom, illustrated by chemistry and numerous facts, (2) the *elasticity* of the atom, proved by the spectroscope, (3) the *open* structure of the atom, in harmony with the transparency of some bodies to light, the free passage of the magnetic disturbance through all bodies, and numerous other facts—not to mention the physical theory of gravity. In short, it would appear that it would be necessary to infer the *existence* of indestructible elastic atoms of open structure, even if the vortex-atom theory (which *explains* this fact) had not been invented.

[2] The writer himself has seen from German comments on Prof. Tait's work, that the passage above referred to [German translation] has been regarded by some as if the difficulty there mentioned were of such a nature as to prevent the practical adoption of the theory.

[1] The writer has had personal experience of this, partly through correspondence, and partly through the literature relating to the subject. Quotations from the writings of Prof. Zöllner especially seem to show a want of appreciation of the *physical* points of the theory at their true value and significance.

[2] As regards sources of information as to the vortex-atom theory, the following may be mentioned. Sir William Thomson, "On Vortex-Atoms," *Phil. Mag.*, July, 1867. Prof. Clerk-Maxwell, article "Atom," *Encyc. Brit.* 1875. The theory is dealt with to some extent in a popular manner in

many investigators in the paths of natural science who may find some difficulty in realising the physical basis and real bearings of the theory, and who nevertheless take a rational interest in the solution it is capable of affording to some of the greatest difficulties of molecular physics. The whole structure of physics may be said to rest upon a *molecular* basis, and therefore the importance of a right view of this basis cannot be over-estimated. The old theory of *perfectly rigid* molecules put an immense difficulty in the way of the development of physical results upon such a groundwork. A theory of *elastic* molecules therefore becomes of the utmost importance as a practical working hypothesis, and the accordance with observation of new results predicted from this hypothesis as a basis, will then form additional confirming illustrations of its truth. The removal of any misunderstandings that might be obstacles in the way of the use of the vortex-atom theory as a working hypothesis becomes, therefore, a point of considerable importance. Those more especially who have handled the spectroscope and viewed the exquisite precision of its results, become impressed with the *certainty* of the groundwork upon which their molecular studies are based, and no less imbued with the conviction of the existence of that *explanation* that forms the basis of the facts that are recorded with such unfailing accuracy.

S. TOLVER PRESTON

COMPARATIVE ANATOMY OF MAN[1]

I.

THE great scope and interest of the subject of anthropology, as well as its most convenient subdivisions, are well illustrated by the prospectus of the teaching at the Anthropological Institute of Paris. There are at present six chairs:—(1) Comparative Anatomy in Relation to Anthropology, by Broca; (2) Biological Anthropology, or the Application of Anatomy and Physiology to Anthropology, by Topinard; (3) Ethnology, or the Study of the Races of Man, by Dally; (4) Linguistic Anthropology, by Hovelacque; (5) Palæontological and Prehistoric Anthropology, by Mortillet; and (6) Demography, which includes what we commonly call social and vital statistics and Medical Anthropology, by Bertillon. These subjects are publicly taught in a school supplied with all necessary appliances, founded partly by private munificence, but also liberally subsidised by the Municipality of Paris and the Department of the Seine. There is also at Paris a complete course of general anthropology given yearly by M. de Quatrefages in connection with the magnificent museum at the Jardin des Plantes. To these institutions we have nothing comparable in England, and neither at our Universities or elsewhere is any branch of anthropological science systematically taught. The present lectures only embrace a small portion of one of the six subdivisions enumerated above, that of biological anthropology. This science is purely one of observation, and in proportion as the materials upon which our observations are founded are multiplied, so will the value of the observations be increased. These materials are collected in museums, which at present in this country are not so complete as might be desired. The largest public collection is that of the College of Surgeons, containing about 1,200 crania of different races; the largest private collection is that of Dr. Barnard Davis, of Shelton in Staffordshire, considerably exceeding that of the College both in number and variety of specimens. Happily these are about to be united, and, under the care of the Council of the College, will be made accessible to all who wish to pursue the study of anatomical anthropology.

an article on "The Atomic Theory of Lucretius," *North British Review*, March, 1868, also by Prof. Tait, in his work "Lectures on Some Recent Advances in Physical Science."

[1] Abstract Report of Prof. Flower's lectures at the Royal College of Surgeons, March 1 to March 29, on the Comparative Anatomy of Man.

Besides the Barnard Davis collection, only a small portion of which has as yet been received, one of the most important additions to the museum since the last course of lectures is a series of skulls collected in the Fiji Islands in 1876 by Baron Anatole von Hügel, forming part of a donation made by Mr. Erasmus Wilson. They consist of sixteen crania of the *Kai Colos*, or mountaineers of the interior of the western portion of Viti Levu, and five crania from the eastern coast and small islands adjacent. The inhabitants of the Fiji group are generally described by ethnologists as a mixed race, compounded of Melanesians and of brown Polynesians, as the islands are situated on the confines of the territories inhabited mainly by these two races, and the few crania hitherto accessible have favoured this view. Those, however, of the Kai Colos brought home by Baron von Hügel, and which probably represent the most primitive native population of the islands, show all the characters of the purest Melanesian type, without the slightest trace of Polynesian mixture. Their purity is shown by their wonderful similarity, and by their very peculiar and strongly-marked characters, discernible with equal facility in both sexes and at all ages. They are large, the average capacity of eight adult males being 1,482 cubic centimetres; and with muscular ridges and impressions strongly developed. In proportion to their length, they are the narrowest crania known, having an average latitudinal index of only 66·3. Not one has the index so high as 70·0, and in one it descends as low as 61·9, which is below that of any other normal skull in the collection. The height in all very considerably exceeds the breadth, the average altitudinal index being 74·1. They thus belong to the most strongly marked *hypsistenocephalic* type. The zygomatic arches are very wide compared with the cranium. The brow ridges are strongly marked, though less so than in the Australians. The orbits are low and quadrangular, the nasal bones short, though rather prominent, and the nasal aperture wide (index 57·1), the jaws prognathous, though not to an extreme degree, and the teeth large. The skeleton of the face thus conforms with what is generally found in the Melanesians or Oceanic negroes, but the features are on a larger scale and more strongly pronounced than in the inhabitants of many of the New Hebridean and Papuan islands. The skull of the Tongans and Samoans, living on islands scarcely 300 miles from the Fijis, presents the greatest possible contrast to that just described. It is short and round (latitudinal index 82·6), the orbits are round, the nasal bones long and flat, and the aperture narrow (index 44·3), and the jaws are not prognathous. It is well known that for a long time the Tongans have been in the habit of visiting the Fijis, especially the smaller islands to the east of the group, and that there is in the inhabitants of that region a considerable infusion of Tongan blood. Five skulls of natives of the small island of Vanua Balavu, where this influence is supposed to prevail, show a distinct deviation in every character from that of the Kai Colos, and these deviations are, without exception, in the direction of the Tongan or Polynesian type. The average latitudinal index is raised to 71·9; the nasal index is 50·0, the orbits intermediate in form, and the prognathism much reduced. No skulls have as yet been examined from the second large island, Vanua Levu, and the numbers of those just described are, perhaps, not sufficient to draw any great conclusions from, but, as far as they go, they tend to show that, so far from the Fijians generally being a mixed race, the mass of those that inhabit the interior of the large islands are remarkably pure, and of the Melanesian or Papuan type in its most characteristic, almost exaggerated, form, but that the natives of the coast districts and outlying islands to the east show certain tendencies towards the brown Polynesian type, and as these are the people with whom European visitors to the Fijis have mostly come

into contact, an undue impression has been created as to the extent of the mingling of the races. At all events, little countenance is given by these facts to the view, which rests chiefly in the interpretation of some ancient legends, that at a former time the Tongan influence was much greater in the Fiji Islands than it is at present.

Races of America.—Two extreme views have been held as to the unity or diversity of the races of man inhabiting the American continent. It has been said on the one hand that "when you have seen one Indian you have seen all," and on the other, that as much difference can be found in the native Americans, as among the inhabitants of the Old World. Both statements are exaggerations, the truth lying between the two. A source of difficulty in studying the cranial conformation of the Americans lies in the wide-spread practice of deforming the head artificially in infancy. This habit prevailed extensively but not uniformly throughout all the western parts of the continent, from Vancouver's Island down to the southern parts of Peru. It also occurred, though less generally, in the southern part of what is now the United States, and in the West India Islands. It was forbidden to the Peruvians in 1585 by the synod of Lima, and again with severe penalties in 1752. In British Columbia it has only recently fallen into disuse. The custom is, or perhaps we may almost say was, not confined to America. Hippocrates and various other writers of his age, speak of the *Macrocephali*, people who dwelt on the eastern shores of the Black Sea, who purposely altered the form of their children's heads. Skulls thus deformed have been found in ancient tombs in the Caucasus (especially near Tiflis) in the Crimea, and, though less numerously, at various places, along the course of the Danube, and extending as far as the south of France. These have been assigned to Avars, Huns, or Tartars, but more probably belong to the Cimmerians, who originally inhabited the region where they are now found most abundantly, and spread westward over Europe some centuries before the Christian era. The custom, though in a modified degree, is scarcely yet extinct in the south of France. Cranial deformation, though usually only of the simple occipital form, is also practised in many parts of Asia and Polynesia, though quite unknown in Africa or Australia.

Many attempts have been made to classify the various kinds of cranial deformation, but as they pass insensibly into one another, it is not very easy to do so. They may, however, for convenience of description be grouped thus: 1. Simple occipital flattening, often probably undesigned, being occasioned by the pressure of the board or hard pillow upon which the child is laid; this is very common among the ancient Peruvians and also among some Mongol tribes and Polynesians. 2. Simple frontal flattening, also common in Peru, though less so than some of the following forms; also among the Caribs and in the island of Mallicollo, in the new Hebrides. 3. Fronto-occipital flattening, with lateral (compensatory) expansion, usually unsymmetrical. This, which may be depressed or elevated according to the point at which the greatest occipital pressure is applied, is the commonest form among the Indians of British Columbia and Vancouver's Island, and is also met with in Peru. The head is compressed between pads of birch bark and moss from birth to the age of twelve months. During subsequent growth it recovers somewhat from the extremely flattened form that it usually presents at that age. 4. Elongation by lateral as well as frontal and occipital pressure. In this form the head is symmetrical, and the sides compressed. It is produced by bandages passing round the forehead, vertex, and occiput, and is variously modified, according to the mode in which these are disposed. The Aymara Indians of the neighbourhood of Lake Titicaca, in Peru, some of the tribes in Vancouver's Island, and the *Macrocephali* of the shores of the Euxine, present examples of this form.

As far as can be ascertained by observations upon the North American Indians, no impairment of the intellect is produced by these strange alterations of the form of the cranium, and consequently of the brain. The families of the chiefs, in which alone it is practised in many tribes, maintain their ascendancy over the lower orders and slaves with undeformed heads. Foville, however, appears to have traced numerous cerebral lesions among the peasant population of France to the custom of tightly bandaging the heads of infants.

No motive can be alleged for this singular and wide-spread practice, except blind obedience to custom or fashion, precisely as in many analogous cases of barbarous distortions or mutilations of parts of the body, the origin of which is lost in the depths of antiquity. Without looking as far off as China, very few men or women in England can boast of feet which are not quite as much altered by artificial compression in youth from the form given by nature as are the heads of the Chinook Indians. The far more injurious constriction of the waist, so commonly practised by women of nations which occupy the highest rank of civilisation yet attained by mankind, is only another example of the same strange propensity to tamper with a form which good sense as well as good taste ought to teach was the most perfect that could be designed.

The natural history of the population of the great American continent, as it existed before the changes wrought by the European conquest, which followed the adventurous voyage of Columbus, offers an interesting but difficult problem to the anthropologist. Do all the various tribes (1,700 are enumerated by Keane, and these must be but a small portion of those formerly existing), extending from the Polar Sea to Cape Horn, through such various climates, and inhabiting regions so diverse in their physical characters, belong, as many writers have averred, to one primary division of the human species, or are they capable of being divided into groups, having as strongly-pronounced distinctive characters as are to be found among the inhabitants of the old world, as has been stated by others? Again, if we find difficulty in dividing them into well-marked groups, do we find such uniformity of characters as to lead to the belief that they are all of common origin, or have we reason to think that they are the result of the mingling together in various proportions in different districts of two or more distinct sources of population? Furthermore, inquiry will naturally be directed to their relation with other people. Whether we consider them as one or as several people, we shall have to ask with which of the races of other parts of the world are they most nearly allied.

The views till lately held as to the peopling of America, though perhaps under various modifications and disguises, may be grouped under two heads:—(1) That the inhabitants of that continent were a distinct auctothonous or indigenous people, created in the country in which they were found, and therefore not related to those of any other land. This is the theory of the polygenistic school, but is probably not held by many scientific men of the present day. 2. The monogenists mostly believed that they are descended from an Asiatic people, who in comparatively recent times passed into America by way of Behrings Straits, and thence spread gradually over the whole continent, as far as Cape Horn, and that their nearest allies must therefore be looked for in the north-eastern regions of Asia. It has also been thought by those who have held the same general views, that at all events a partial peopling of the American continent may have occurred from Southern Asia, by way of the Polynesian Islands, or from North Africa, across the Atlantic. The discovery of the great antiquity of the human race in America, as well as in the Old World, has led to an

important modification of these theories. The proof of a very considerable antiquity rests upon the high and independent state of civilisation, which had been attained by the Mexicans and Peruvians at the time of the Spanish conquest, and the evidence that that civilisation had been preceded by several other stages of culture, following in succession through a great stretch of time, but the antiquity of the quasi-historical period thus brought out, is entirely thrown into the shade by the evidence now accumulating from various parts of the United States, Central America, and the Pampas, that man existed in those countries, and existed under much the same conditions of life, using precisely similar weapons and tools, as in Europe, during the pleistocene or quaternary geological period, and, perhaps, even further back in time. As in Europe his works are found associated with the remains of *Elephas primigenius*, and other extinct mammals, so in America are they found in contemporary deposits with those of *Elephas columbi*. If the inductions commonly made from these discoveries be accepted, and the fact admitted that men lived both in Europe and America before the surface of the earth had assumed its present geographical conformation, the data from which the problem of the peopling of America is to be solved are altogether changed. Recent palæontological investigations, especially those carried on with such great success in the neighbourhood of the Rocky Mountains, show that an immense number of forms of terrestrial animals that were formerly supposed to be peculiar to the Old World are abundant in the New; indeed many, such as the horses, rhinoceroses, camels, &c., are more numerous in species and varieties in the latter, and therefore the means of land communication between the two must have been very different to what it is now. Taking all circumstances into consideration, it is quite as likely that Asiatic man may have been derived from America, as the reverse, or both may have had their source in a common centre, in some region of the earth now covered with sea.

However this may be, the population of America has been for an immense period practically isolated from the rest of the world, except at the extreme north. Such visits as those of the early Norsemen to the coasts of Greenland, Labrador, and Nova Scotia, or the possible accidental stranding of a canoe containing survivors of a voyage across the Pacific or the Atlantic, can have had no appreciable effect upon the characteristics of the people.

The evidence derived from the study of the physical characters of the Americans shows that there is, considering the vast extent of the country they inhabit, and the great differences of climate and other surrounding conditions, a remarkable similarity in essential characters, with, at the same time much diversity in detail, and in other characters which perhaps are not of such primary importance as has often been thought. The construction of the numerous American languages, of which as many as 1,200 have been distinguished, is said to point to unity of origin, as, though widely different in many respects, they are all, or nearly all, constructed on the same general grammatical principle, that called *polysynthesis*, which differs from that of the languages of any of the Old World nations. In mental characteristics all the different American tribes have much that is in common, and the very different stages of culture to which they had attained at the time of the conquest, as that of the Incas and Aztecs, as contrasted with that of the hunting and fishing tribes, which has been quoted as evidence of diversity of race, were not greater than those between different nations of Europe, as Gauls and Germans, and Greeks and Romans in the time of Julius Cæsar; yet all these were Aryans, and in treating the Americans as one race, it is not intended that they are more closely allied than the different Aryan people of Europe and Asia.

The physical or anatomical characters of the American native people, taken as a whole (leaving out for the present the Eskimo), may be thus described:—In stature there is considerable variation. Among them are the tallest known people on the earth, the Tehuelches or Patagonians, who, though not the fabled giants of the early voyagers, appear, by all trustworthy accounts, to attain an average (for the men) of from 5 feet 10 inches to 6 feet, which exceeds that of any other race. Some of the North American Indians are also very tall, 381 Iroquois carefully measured during the late war giving a mean height of 5 feet 8·3 inches. On the other hand, the Fuegians, and especially the Peruvians, are small, the latter not averaging more than 5 feet 3 inches. There is, however, no pigmy race on the American continent, like the Bushmen, Negritos, and Lapps of the old world.

The hair, always a character of primary importance in zoological anthropology, is remarkably uniform. Its prevailing, if not universal, colour is black, or intensely dark brown. The pale and auburn colour of the hair of Peruvian mummies is probably due to accidental bleaching, and the fair hair, said occasionally to be met with in existing tribes, may be the result of European admixture. It is always straight and lank, though sometimes coarse and sometimes silky in texture, a variation dependant upon the thickness of the individual hairs. In transverse section it approaches the circular form, perhaps more nearly than in any other race, though in this and other characters it resembles that of the Asiatic Mongolian people. On the scalp the hair grows abundantly and often to a great length; in many North American Indians it has been known to trail upon the ground when standing upright. Not less characteristic is the rarity or absence of hair on the face and other parts of the body. The skin is smooth and soft, and of various shades of brown, though cinnamon (commonly called *copper* colour) is the most characteristic. Some Californian Indians and the now extinct Charruas of Uruguay were said to be nearly black; and some scattered tribes, both in North and South America, are described as being nearly as fair as Southern Europeans. The shade of the colour appears to have no relation to the external conditions, such as heat, moisture, &c. Though the features of various tribes, and of particular individuals in each tribe, show considerable diversity, a characteristic type prevails throughout the great majority of the whole people from north to south. The forehead is usually retreating; the face wide in the malar region, narrowing towards the chin; the brows prominent, overshadowing rather small, sleepy, half-closed eyes; the nose long from above downwards, and narrow; the dorsum, as seen in profile, usually arched, rather sunk at the root, then projecting somewhat horizontally, and making a tolerably sharp bend down to the tip, which is not produced down below the septum; though this form is very frequently met with among all tribes, there is some diversity, and the profile is sometimes simply arched and sometimes straight, but a broad flat nose is very rarely met with; the mouth is wide and prominent, the lips rather thin; the chin well formed, narrow, but prominent; the whole face below the eyes long and large, the malar bones projecting laterally, and the lower jaw large.

(*To be continued.*)

VARIATIONS FROM MARIOTTE'S LAW

THE universal application of the law enunciated by Mariotte and Boyle, that the "volume of an aeriform body is inversely as the pressure to which it is exposed," was brought into question at an early date after the publication of the famous experiments on which the principle was based. Oersted and Schwendsen established in 1826 for easily liquefiable gases that the elasticity does not keep pace with the pressure. At about the same

time Despretz showed that notable variations took place in the case of air above a pressure of fifteen atmospheres. Arago and Dulong, intrusted by the French Academy with the verification of these observations, carried out a carefully conducted series of experiments on the compressibility of air extending up to twenty-seven atmospheres, but came, however, to the conclusion that Mariotte's law was correct. This opinion was strengthened by Pouillet's researches in so far as it related to the then so-called permanent gases, while confirmatory evidence was brought in favour of Oersted and Schwendsen's experiments on easily liquefiable gases. This view of the correctness of the law for a certain group of gases was held by the scientific world until 1845, when Regnault, by a brilliant series of experiments of the most exact kind, showed that air, nitrogen, and carbonic acid experienced a constant decrease of elasticity when submitted to pressures rising to thirty atmospheres, while under the same conditions a regular increase of elasticity in the case of hydrogen occurred. A few years later Natterer of Vienna published some remarkable experiments on the compressibility of gases, making use for the first time of enormous pressures, reaching in several cases nearly 2,800 atmospheres. While Natterer's methods of measurement were by no means exact, the results of his experiments showed beyond doubt that for pressures above eighty atmospheres oxygen, nitrogen, and carbonic oxide possessed the same peculiar property manifested ordinarily by hydrogen, viz., the volume of the compressed gas being greater than that demanded by Mariotte's law. The verification of Natterer's

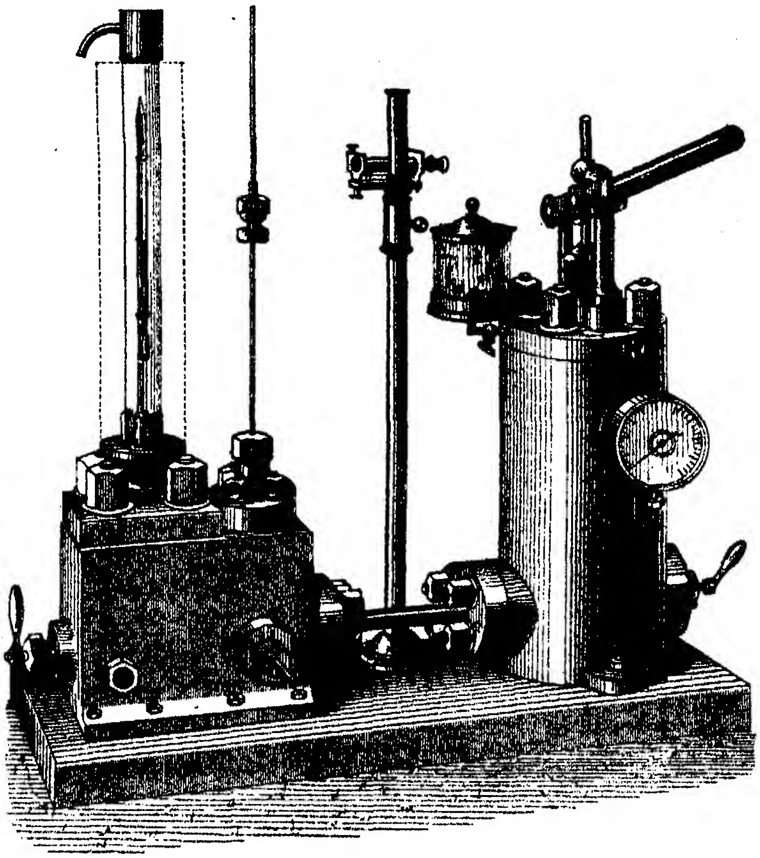

Fig. 1.

results was undertaken in 1870 by Cailletet, whose name has been so prominent of late years by his success in liquefying the so-called permanent gases. By making use of one of Desgoffe's manometers he experimented on air and hydrogen up to 600 atmospheres, and obtained figures comparing very closely with those published by Natterer.

So much for the data on this subject up to within a recent period. While the general truth of the results chronicled by Natterer and Cailletet was accepted by the physical world, it was still regarded as of prime importance to carry out the experiments under the influence of pressures with regard to the measurements of which there could be absolutely no doubt. The only practicable method of attaining this end was evidently to make use of enormously high columns of mercury. In 1875 Dr. Andrews attempted the solution of the problem in this manner, but was forced to succumb before the mechanical difficulties attendant upon its execution. The French physicist M. E. H. Amagat, who has devoted his attention for a number of years past to the phenomena of compressibility, appears to have been more successful in overcoming the manifold obstacles in the way of accomplishing the task, and furnishes[1] an interesting account of what is certainly one of the most remarkable *tours de force* of modern experimental physics. It consisted in making exact measurements of the changes in volume of gases when submitted to the pressure of a column of mercury of over *one-fifth of a mile* in height. In order to give a correct idea of the conditions under which Amagat's important results have been obtained, we will describe briefly the three essential elements of the experiments: the locality, the column of mercury, and the apparatus for receiving the pressures, communicating them to the gases operated upon, and measuring the

[1] *Annales de Chimie et de Physique* [5], xix. 345, Mars, 1880.

changes in volume. The latter (Figs. 1 and 2) consisted of a massive block of cast iron containing two cavities; one (C) for the reception of the extremity of the column of mercury, the second (D) for the reception of the graduated tube (M) inclosing the gas to be experimented upon. A narrow passage connects the two with each other and (F) with the reservoir of a powerful pump, while conical screw-taps (P′, P″) manipulated from the outside permit the openings into the cavity beneath the column of mercury or into the reservoir of the pump to be closed at will. The manometer (M) containing the gas to be compressed is of glass tubing, having an internal diameter of 1 millimetre and an external diameter of 10 millimetres, and is graduated for a distance of 50 centimetres. It is inserted hermetically into a massive bolt (B), which enters into the second cavity (D) of the apparatus. The free portion of the manometer is inclosed by a roomy glass tube, through which flowing water maintains a constant temperature, and that in turn by a copper cylinder, to guard against accidents. Mention can only be made

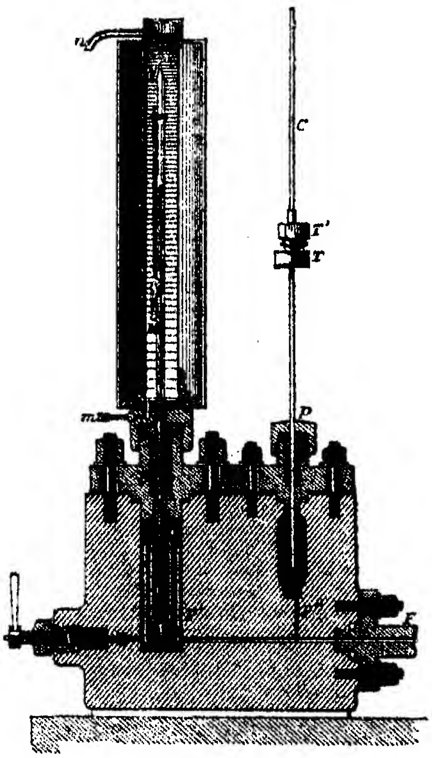

Fig. 2.

here of the ingenious devices for closing hermetically all the joints. The second important feature, the tube (C) for containing the column of mercury, is formed of pieces of steel tubing—internal diameter 2 millimetres, external 5 millimetres—united by specially prepared joints, which, while closing hermetically, are still easily attached or detached. The place chosen for the most noteworthy experiments was the coal-mine of Verpilleux, in the neighbourhood of St. Étienne. This pit reaches a depth of 327 metres, and a constant temperature prevails at the bottom.

The experiments made here were confined to nitrogen gas. The chief features of an experiment are as follows:—A vessel containing warm, dry mercury is placed in the large cavity (D) of the apparatus. The manometer containing dry pure nitrogen and terminating in a capillary point is then introduced beneath the mercury, the point is broken off, and the bolt inclosing the manometer is screwed into its place. Sections of the steel tubing (C) are then screwed on, one above the other. After the addition of each section mercury is forced into the apparatus by the pump, and mounts to the top of the tube; the height of the column of mercury is measured, the volume of the compressed gas is read off by means of a cathetometer, and thus the series of observations proceeds slowly until the mouth of the pit is reached. As can easily be imagined, such experiments in the shaft of a coal-pit are by no means easy or pleasant to perform. We can here allude only to the numerous elaborate precautions taken by M. Amagat to insure accuracy in measurement and reduce all possible causes of error to a minimum. The divergences in corresponding series of observations never exceeded one-tenth of 1 per cent.

Coming now to the results of the experiments made on the compressibility of nitrogen at Verpilleux, we notice, firstly, that the compressibility increases slowly until it reaches a maximum at about 65 atmospheres; secondly, that it decreases equally slowly until it reaches a normal figure at about 91 atmospheres; and thirdly, that after passing this point it decreases rapidly until at 430 atmospheres the volume of compressed gas is five-fourths of what it would be if Mariotte's law were true. In the following table the first column contains the pressures in atmospheres of the column of mercury, the second those deduced according to Mariotte's law from the corresponding volumes of compressed nitrogen, and the third the differences between the two:—

Pressures observed.	Pressures calculated.	Differences.
27·289	27·289	0·000
46·496	46·580	+ 0·084
62·034	62·251	+ 0·217
73·001	73·181	+ 0·188
80·580	80·728	+ 0·140
90·975	90·978	+ 0·003
109·171	108·665	− 0·506
126·896	125·388	− 1·508
168·810	162·835	− 5·975
208·635	196·224	− 12·411
251·127	229·271	− 21·855
290·934	256·669	− 34·275
332·039	282·544	− 49·495
373·302	306·055	− 67·247
430·773	335·707	− 95·066

After having established the above table of the changes in the compressibility of nitrogen, M. Amagat was in a position to study the analogous phenomena in the case of other gases with much greater ease. For this purpose it was simply necessary to replace the tube for the column of mercury in the apparatus just described by a manometer filled with nitrogen, the counterpart of that used for the gas under examination. By means of these modifications of his original apparatus M. Amagat has prepared very accurate tables for the changes in compressibility up to 400 atmospheres of air, oxygen, hydrogen, carbonic oxide, ethylene, and marsh gas. In M. Amagat's graphic delineation of the variations from Mariotte's law in the cases of the seven gases mentioned, the abscissæ correspond to the pressures in metres of mercury, while the ordinates correspond to the difference between the products of the pressures into the volumes and unity, *i.e.*, to the variations from Mariotte's law. They all start from a common point—a pressure of 24 metres. The curves of nitrogen and hydrogen are however continued to a minimal measure in accordance with Regnault's data. The minimum ordinate of the ethylene curve, which is 425, could not easily be given.

In glancing over the curves we see that the most conspicuous variations occur in the case of those gases most nearly approached to the conditions of liquefaction. The variations in the curve of oxygen are much more

marked than in that of nitrogen, while the curve of air lies between the two. Further, hydrogen is the only gas not exhibiting a minimum of the product of pressure and volume. As hydrogen is, so to say, the most perfect gas known, it would seem probable that on being forced to assume a state of tenuity allied to that of hydrogen, *i.e.*, by being exposed to elevated temperatures, the other gases experimented upon would yield curves resembling more and more that of hydrogen, until finally temperatures would be attained at which the convexity of the curves would totally disappear. The results chronicled by M. Amagat, taken in connection with those ascertained by other investigators in experimenting upon gases compressible at ordinary temperatures, would fairly allow the establishment of a law that when a gas on being compressed gives constantly increasing numbers for the product of the pressure by the volume—which according to Mariotte's law should remain unity—it is at a temperature above its critical point; or, to use Dr. Andrews' apt description, without actual liquefaction it can pass by means of pressure alone through all the intermediate stadia between the gaseous and the liquid states.

M. Amagat's interesting researches will, it is to be hoped, be followed by similar experiments executed under a wider range of temperature on the various gases; the results of which will, without doubt, throw much valuable light on the phenomena and conditions of liquefaction. Apart from their purely scientific interest, the tabulated records of his observations furnish to the engineer data of the greatest value, enabling him to construct manometers combining exactness and delicacy for the indication of high pressures, which hitherto have been measured with but a certain degree of approximation to the truth.

T. H. N.

NOTES

Dr. M. Treub has been appointed director of the Botanical Gardens at Buitenzorg, Java.

We are glad to learn that the collections from Socotra, which Prof. Bayley Balfour was compelled to send by sea from Brindisi, have arrived safely at Kew Gardens.

At Dorpat a monument is about to be erected to the memory of the celebrated naturalist, Karl Ernst von Baer, who died at Dorpat on November 28, 1876. The funds will be supplied by the Dorpat University and the Imperial Academy of Sciences at St. Petersburg. The eminent sculptor, Herr Franz von Villebois, has made two excellent sketches for the monument.

At a recent meeting of the Court of Common Council, at which the Lord Mayor presided, it was resolved that the freedom of the City of London in a suitable gold casket be presented to Sir Henry Bessemer, F.R.S., M.I.C.E., in recognition of his valuable discoveries, which have so largely benefited the iron industries of this country, and of his scientific attainments, which are well known and appreciated throughout the world.

On August 5, as we have already announced, the exhibition of anthropological and prehistoric objects found in Germany will be opened at Berlin. At the same time the general meeting of the German Anthropological Society will take place. No less than 114 archæological, eight palæontological, and sixteen craniological museums will send objects to this exhibition. The objects found in the Loess strata will be particularly interesting, and besides these we may point to the objects found in caves and in moors.

The British Medical Association will be well received at Cambridge in August, not only by the University but in the town; the Town Council have granted the Guildhall free of cost. The president of the Physiological Section, Dr. Rutherford, will give his address on Wednesday, August 11, at 2 o'clock, and there will follow a discussion on the subject, "Is Urea formed in the Liver?" to be opened by Prof. Gamgee, of Manchester; on August 12 Prof. W. Preyer, of Jena, will open a discussion on "Sleep and Hypnotism." Drs. Gaskell (Cambridge) and Stirling (Aberdeen) are the secretaries of this Section.

Prof. Milne, of Tokei, Japan, who has made a trial of almost every seismoscope in existence, and has devoted all his leisure to seismometry for several years, has exerted himself successfully to interest the Japanese officials in establishing a suitable system of earthquake observation, as well as the Europeans in Japan, who have lately formed a society for the purpose of systematically studying seismic phenomena. Mr. Milne has obtained the assistance of the Government in having immediate telegraphic communication concerning earthquakes, and he aims at getting from telegraph operators throughout the country information concerning earth-currents during earthquakes. If we consider the importance of studying the matter systematically in a country where small earthquakes occur every few days, and where the people are all greatly interested, it must be evident that this society will have a promising future.

A Congress of the Members of the Royal Agricultural College, Cirencester, of former Students and Professors of the College, and of others interested in Agriculture, will be held in the College on Friday, June 4, 1880, under the Presidency of the Principal. At the Morning Session at 10 a.m. the subject for discussion will be—"Diseases in Cattle and Sheep, with especial reference to recent outbreaks," introduced by a paper by Prof. Buckman, F.G.S., F.L.S., on "The Natural History of Meadow and Pasture, in connection with such Diseases." At the afternoon session at 3 p.m. the subject for discussion will be—"Agricultural Research and Experimental Stations," introduced by Prof. Henry Tanner, M.R.A.C., F.C.S.

In connection with the subject of "Fungus Inoculation of Insects," a Heidelberg correspondent, "O. S.," sends us for publication the following beautiful and little-known poem, by Goethe (1810, Poems, vol. ii.):—

Der Fliegentod

"Sie saugt mit Gier verräth'risches Getränke
Unabgesetzt, vom ersten Zug verführt;
Sie fühlt sich wohl, und längst sind die Gelenke
Der zarten Beinchen schon paralysirt;
Nicht mehr gewandt, die Flügelchen zu putzen,
Nicht mehr geschickt, das Köpfchen aufzustutzen—
Das Leben so sich im Genuss verliert.
Zum Stehen kaum wird noch das Füsschen taugen;
So schlürft sie fort und, mitten unterm Saugen,
Umnebelt ihr der Tod die tausend Augen."

Dr. Werner Siemens, the well-known German electrician, had been instructed, a few years ago, to manufacture a series of standard weights on behalf of the Egyptian Government, which wished to adopt the German system; but as the Egyptian Government did not fulfil its financial obligations Dr. Siemens kept the set of weights in his workshop, where they were used for various purposes. On the occasion of the visit of the weights and measures inspector these weights were discovered, and Dr. Siemens summoned before the police. The case has been tried with some solemnity, and Dr. Siemens fined 2 marks.

A remarkable phenomenon was observed at Kattenau, near Trakehnen (Germany), and in the surrounding district, on March 22. About half an hour before sunrise an enormous number of luminous bodies rose from the horizon and passed in a horizontal direction from east to west. Some of them seemed of the size of a walnut, others resembled the sparks flying from a chimney. They moved through space like a string of beads, and shone with a remarkably brilliant light. The belt containing them appeared about 3 metres in length and ½ metre in breadth.

The Mitchell Library of Glasgow, which was opened in 1877, has already attained considerable dimensions, and under the careful organisation of the principal librarian, Mr. Barrett, promises to be of great service as a consulting library. It now possesses 16,828 works, or 27,982 volumes, a large proportion of which are scientific. Of the volumes issued in 1879 19½ per cent. belonged to the division of "Arts, Sciences, and Natural History"—rather a curious division, by the by. This percentage was excelled only by History, Biography and Travel, and "Miscellaneous."

The eminent physicist, Dr. Rudolf Clausius, of Bonn, has been elected a member of the Roman Academy "dei Lincei."

The Secretary of State for Foreign Affairs of the Republic of San Domingo has issued a circular to the Ministers of England, America, France, Italy, Spain, Holland, and Denmark, soliciting their co-operation in the erection of a monument to Christopher Columbus in the city of San Domingo.

The Lisbon Academy has decided to ask the consent of the Government to transfer the bones of Vasco da Gama from Vidigueira Alemtejo to the church of the Jeronimites, Belem. It is proposed that a deputation of the Academy should accompany the remains of Vasco da Gama, and a war ship convey them from Bareira, on the banks of the Tagus, to the Lisbon Arsenal.

Admiral Mouchez, the Director of the Paris Observatory, has published a pamphlet on the work executed in this establishment during the year 1879. A new decree quoted by M. Mouchez arranges that the several *employés* of the Observatory, when not too old, can be admitted to follow the course of lectures given at the School of Astronomy recently created, and are fit to be appointed astronomers if successful in their examinations. The establishment is to be enlarged in the vicinity of Boulevard Arago, the admission of the public to be more frequent, and the magnetical observations to be resumed. The meteorological observations have been continued, and are to be in some respects enlarged, although no change is contemplated in the organisation of the Bureau Centrale and the Service d'Avertissements, which will continue for ever independent of the astronomical observatories.

The *Sydney Morning Herald* records the death of Mr. Edward Smith Hill on March 17, sixty-one years of age. He was a native of Sydney, and after retiring from business devoted his time to scientific investigations for the last eighteen years. He made a voyage to the South Sea Islands, and wrote some valuable papers and pamphlets on their flora. He wrote for the New South Wales Government a report on the flora of Lord Howe Island, and the condition of its European inhabitants. Among his contributions to Sydney journals was a series of articles describing the fishes found in the harbours and rivers of New South Wales and along the coast.

The work of examining the 5,000 *employés* of the Pennsylvania Railroad Company as to their power of distinguishing colours and forms was begun in Jersey City on April 1. Acuteness of vision was tested by means of printed cards placed at a distance of twenty feet; also by means of small openings in a screen illuminated on the further side. Many who successfully passed these ordeals failed signally in the colour tests. Three skeins of woollen yarn were used, one being light green, the second rose, and the third red. Each of these was placed on a table in front of the person examined, at a distance of three feet, and, with the vision of either eye obstructed by a spectacle frame, the man was requested to name the colours, also to pick out a similar shade to one or other of the three specified from different skeins of woollen yarn numbered from 1 to 36. One young man correctly designated the test skein as red, but on being told to select a similar shade from the skeins before him, he picked three shades of blue, two of yellow, and one of red. He could distinguish no difference; and the same thing happened to half-a-dozen others who followed him. The skeins in the row were then divided into three sets with twelve numbers in each. Some men proved able to distinguish all the shades of green, but failed lamentably in picking out the different shades of red. The officers of the road were greatly impressed, it is said, by the results obtained.

On April 1 a "Society for Zoology" was formed at Berlin, with a view of furthering zoological science and zoological research in all its branches. The president is Dr. Eduard Kaiser (27, Friedrich Strasse), who will furnish all particulars to intending members.

At Paris a Society "contre l'abus du tabac" has been formed, which intends to combat the excessive indulgence in smoking which has of late become the fashion in almost the whole of Europe. The Society offers various prizes for treatises on the human health and the dangers it is subject to from excessive use of tobacco.

The *Times* Geneva correspondent writes, under date May 12, that a few days before, during a violent thunderstorm, a tall poplar on the Cour de Rive, a street in the upper part of Geneva, was struck by lightning. Directly after the occurrence Prof. Colladon made a minute examination of the tree. The Professor states that it is not true, as has been commonly supposed, that the gashes (*plaies*) found in the trunk of a tree which has been struck by lightning are the parts with which the lightning first came into contact. The parts first struck are the highest branches, especially those most exposed to the rain. Thence it runs down the smaller branches—affecting almost the whole of them—to the larger ones, until it reaches the trunk. These larger branches, and above all the trunk, being much worse conductors than the small branches, the passage through them of the electricity produces heat and "repulsive effects," whereby the bark and sometimes the wood are torn in pieces, the bits being thrown a considerable distance, occasionally more than 50 metres. It not infrequently happens that the upper branches and their leaves are destroyed—this is generally the case with oaks, which are often struck—but the leaves and young shoots of poplars and many other trees are such excellent conductors that they do not appear when struck to suffer any notable injury. This finds full confirmation in the condition of the poplar on the Cour de Rive. In this instance the principal and highest branch of the tree on its south-western side was the first with which the lightning came in contact. Its leaves and twigs, neither withered nor tarnished, were torn into minute fragments and scattered about on the ground. This was the effect, not of the lightning, but of the concussion of air, exactly as if there had been an explosion of dynamite or gunpowder; and the windows of two houses close by were broken in the same manner and by the same cause. The presence of water near the root of a tree is often the determining cause of its attraction for the electric fluid; and the Professor found, 5 metres from the poplar, on its north side, a leaden water-pipe, and close to it a drain filled with waste water from a laundry. The principal fissure in the tree was also on the north side; and half-way between it and the water-pipe a plank lying on the ground had been pierced by a concentrated jet of the electricity as it flashed towards the pipe by the shortest route. Large trees, especially tall poplars, placed near a house, may serve as very efficient lightning conductors, but always on the indispensable condition that there is no well or running water on the opposite side of the house, for in that case the lightning, if it struck the tree, might pass through the building on its way to the water. In erecting lightning conductors it is desirable that their lower extremities should terminate in a stream, a well, or a piece of

damp ground. The plant most sensible to electricity is the vine. When a stroke of lightning falls in a vineyard the leaves affected are turned red-brown or deep green, a circumstance which shows, in the opinion of Prof. Colladon, that the electricity descends in a sheet or shower, and not in a single point, the number of vines touched—sometimes several hundred—by a single *coup* proving that the lightning has covered a wide area.

THE oldest librarian of the Royal Library at Berlin, Dr. Buschmann, died recently at the advanced age of seventy-five years.

A NEW "Illustrirte Naturgeschichte der Thiere," by Philipp Leopold Martin, with numerous illustrations by F. Specht, R. Friese, R. Kretschmer, A. Göring, and L. Martin, jun., will soon be published in two volumes (or fifty parts), by F. A. Brockhaus, of Leipzig. The first volume will contain the chapters on mammals and birds; the second the remaining vertebrates and the whole of the invertebrates.

THE Archæological Society of Athens has purchased about half the village which stands upon the ruins of the Temple of Eleusis. The Society intends building new dwelling-houses in another part, and to begin with excavations as soon as the present inmates of the village have moved.

THE astronomer, Herr Rudolf Falb, well known through his theory of earthquakes, has returned from his South American exploring tour, which extended over a period of more than two years. In his researches he was led in the direction of ethnography and linguistics, and believes that he has made interesting discoveries regarding "the original language of the human race."

IN the vicinity of Milan pile-dwellings have been discovered in a peat-moor, and the foundations of a Roman theatre in the city itself.

"DIE deutsche Arbeit in fremden Erdtheilen" is the title of an interesting lecture recently delivered by Dr. Karl von Scherzer at the Leipzig Gemeinnützige Gesellschaft. It is published by Rossberg, of Leipzig.

THE new Indian Section of the South Kensington Museum, formed from the late India Museum, was opened to the public on Monday.

IT has been resolved to establish a Museum of Science and Art in Aberdeen.

AN experimental department has been established at the Conservatoire des Arts et Métiers in the large hall, where the engines are set in operation every Sunday and Thursday from eleven to six o'clock. Advantage has been taken of the motive power to put in operation a number of Gramme and Alliance machines. After having been exhibited during a fortnight, the instruments will be replaced by others, and so on indefinitely.

DR. JAMES GEIKIE, F.R.S., has been elected President of the Perthshire Society of Natural History, in succession to the late Sir Thomas Moncrieffe. From his address at the annual meeting of the Society we are pleased to see that the local museum to be established by this enterprising Society is making good progress, and promises very soon to be a *fait accompli*. Dr. Geikie gave expression to some wholesome truths as to the functions of such a local museum, the great purpose of which ought to be to fully illustrate the natural history, geology, and antiquities of the surrounding region. This, we are glad to think, is what the Perth Museum promises to be, and it ought, therefore, to prove one of the best local museums in the kingdom, seeing that all in all, from a scientific point of view, Perth is probably the most comprehensive and representative county, as it is among the largest, in our islands.

IN a gravel pit near the town of Posen a mammoth-skull has been discovered, but unfortunately in pieces. Most of the pieces, however, are well preserved—the facial bones alone weigh 28 lbs.

AN earthquake, accompanied by a loud subterraneous noise, is reported from Ilanz, in the Swiss canton of Graubünden. It occurred on April 27 at 3.30 a.m. A smart earthquake shock, coinciding with that at Villeneuve, and accompanied by subterranean noises, was felt at Jarasp and Ardez, in the Engadine, on the 7th inst.

THE centenary of the birth of Gotthilf Heinrich von Schubert, the celebrated naturalist, was celebrated at Hohenstein on April 26. A monument of Schubert was unveiled, and some 500*l*. have been collected for the foundation of a preparatory school for little children, under the name of Schubert-Stift.

A NEW French Society of Agriculture, "The National Society for the Encouragement of Agriculture," held its first meeting on May 15 at the Hôtel Continental, Paris, M. Fouche de Careilles, Senateur, in the chair. The President of the Republic and the most prominent members of the French Government are said to take interest in the new society.

AN ostrich, long on exhibition at Rome, having been suffocated by thrusting its neck between the bars, there were found in its stomach four large stones, eleven smaller ones, seven nails, a a necktie pin, an envelope, thirteen copper coins, fourteen beads, one French franc, two small keys, a piece of a handkerchief, a silver medal of the Pope, and the cross of an Italian order.

A REMARKABLE discovery has recently been made near Hirschberg, in the Riesengebirge (Silesia). In a locality called Weltende, at the entry into the narrow rocky mountain ravine through which the Bober flows, a large heap of bones of diluvial mammals was found, such as pieces of reindeer horns and bones of *Elephas primigenius*, prehistoric ox, &c. The discovery is important, because it proves the former occurrence of the large mammals of the diluvial period even in this elevated valley of the Sudeten mountain-chain.

DR. BECLARD has introduced at Paris, in the buildings where the old Rollin College has been so long established, a new mode of demonstration for physiological experiments on living animals. A circular barrier has been erected round a space where a movable table is arranged on rails. The animal being placed on the table, it is easy to understand that the experiments can be witnessed by each pupil consecutively.

NEAR Bautzen (Saxony) an ancient burial-ground has been discovered. Up to the present not less than 400 antique objects, such as urns, well-preserved "tear-vases," sixteen bronze and iron rings, a head ornament, needles, and buttons were found.

THE additions to the Zoological Society's Gardens during the past week include a Pig-tailed Monkey (*Macacus nemestrinus*) from Sumatra, presented by Mr. J. M. Donovan; a Bennett's Gazelle (*Gazella bennetti*) from India, presented by Mr. Harvey Chevallier; four Rose-coloured Pastors (*Pastor roseus*) from Smyrna, presented by Mr. M. S. Bayliss, C.M.Z.S.; six Paradise Whydah Birds (*Vidua principalis*), two Yellow-backed Whydah Birds (*Coliopasser macrurus*), a White-winged Whydah Bird (*Urobrachya albonotata*), twelve Red-beaked Weaver Birds (*Quelea sanguirostris*) from West Africa, presented by Mr. J. Colman, C.M.Z.S.; a Goffin's Cockatoo (*Cacatua goffini*) from Queensland, presented by Mr. W. T. Green; three Young Lions (*Felis leo*) from Africa, a Grey-cheeked Monkey (*Cercocebus albigena*) from West Africa, a Red-throated Amazon (*Chrysotis collaria*) from Jamaica, deposited; two Common Bluebirds (*Sialia wilsonii*), two Yellow-legged Herring Gulls (*Larus cachinnans*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

THE TRANSIT OF MERCURY, MAY 5-6, 1878.—An Appendix to the "Washington Observations, 1876," is devoted to reports on telescopic observations of this transit and discussions of them. There are individual reports from Professors Asaph Hall, Harkness, Eastman, and Holden, and from Dr. Henry Draper and Mr. H. M. Paul. Probably no other phenomenon of the kind has been watched by so large a number of observers, 109 names appearing in the general record. They were, with very few exceptions, stationed at different points in United States territory. The observations have been calculated by Prof. Eastman and Mr. Paul: the former, attaching greater weight to a certain number made by more experienced observers, finds for the Washington geocentric times those given in the second column below; Mr. Paul deduces for the most probable values those given in the third column (the time of first external contact depending on only two or three observations being omitted; the other contacts depend on 57, 52, and 8 observations respectively):—

	Eastman. h. m. s.		Paul. h. m. s.
First external contact	... 22 4 42·0	...	——
First internal "	... 22 7 42·1	...	22·7 40·61 ± 0·46
Second internal "	... 5 35 27·8	...	5·35 28·83 ± 0·48
Second external "	... 5 38 25·7	...	5·38 29·52 ± 1·18

If the first series of times are compared with the figures in the *American Ephemeris*, which depend upon the earlier theory of Mercury of Leverrier, the errors of prediction are respectively + 77s., + 84s., + 110s., and + 119s. These differences are greatly diminished if the times are compared with those resulting from Leverrier's later theory involved in the tables in the Paris *Annales*, vol. v., as used in the *Nautical Almanac*, more especially if the solar semi-diameter employed is diminished by 2″·0, so as to make the results more strictly comparable with those of the *American Ephemeris*: we have then for the errors of computation, + 2s., + 9s., + 25s., + 34s. The superiority of the later theory is thus evident, and it will be remembered that this theory involves the increased motion of the perihelion of mercury, which induced Leverrier to suspect the existence of one or more planetary bodies, or of matter in some form between Mercury and the Sun.

We may add that if the positions of the planet in the *Nautical Almanac* are combined with the semi-diameters of sun and planet inferred by Leverrier from the transits, the computed times of the internal contacts exhibit differences of + 19·8s. and + 16·4s., the first agreeing closely with the corresponding one deduced from observations in Europe.

THE SECOND COMET OF 1880 (SCHABERLE, APRIL 6).—On the evening of May 8 this comet passed nearly over a star of the eighth magnitude, No. 6815-6 of Oeltzen's Argelander (= 901 of Fedorenko), and Major Tupman, R.M.A., availed himself of this somewhat unusual opportunity for fixing the place of a comet with great precision. By twenty comparisons, ten before and ten after the conjunction in declination, it was found that at 10h. 16m. 17s. Greenwich mean time, the comet followed the star 2·80s. and was 2″·2 south of it.

The following ephemeris, for Greenwich midnight, is derived from elements which represent the observations pretty accurately up to May 8:—

	Right Ascension. h. m. s.	Declination. ° ′	Log. distance from the Earth.	Sun.
May 20	... 6 22 53 ...	+56 43·7 ...	0·38965 ...	0·27695
22	... 6 23 57 ...	55 49·4		
24	... 6 25 3 ...	54 56·6 ...	0·39725 ...	0·27379
26	... 6 26 10 ...	54 5·2		
28	... 6 27 17 ...	53 15·1 ...	0·40432 ...	0·27090
30	... 6 28 24 ...	52 26·4		
June 1	... 6 29 32 ...	+51 38·8 ...	0·41084 ...	0·26829

It appears not improbable that this comet may be observed until towards the end of the year, arriving at its least distance from the earth early in November, and at the same time attaining its greatest intensity of light. It will be lost from proximity to the sun's place for several weeks about the perihelion passage, which is likely to occur about July 1, becoming visible again at the beginning of August in the morning sky. The orbit upon which the above places are calculated gives for the position on August 5 at 12h. G.M.T., right ascension 6h. 58·7m., declination + 31° 52′. The intensity of light on May 8 was about one-third less than is assigned for the first week in November.

PROF. C. A. F. PETERS.—We regret to have to record the death of Prof. Christian August Friedrich Peters, formerly of the Russian Central Observatory at Pulkowa, subsequently Professor of Astronomy in the University of Königsberg, and Director of the Royal Observatory at Kiel, and for upwards of twenty-five years editor of the *Astronomische Nachrichten*. After a long illness he died on the 8th of the present month, in his seventy-fourth year. We reserve a notice of Prof. Peters' principal astronomical work until next week.

GEOGRAPHICAL NOTES

BEFORE starting on his journey from Lake Nyanza to Lake Tanganyika, which we have previously referred to, Mr. J. Stewart, of Livingstonia, spent some time in examining the country on the west of the upper portion of the former lake. He started from Kaningina, and crossed the mountain of the same name at an elevation of about 5,000 feet. After a visit to Chipatula's village he entered Mombera's territory in the Kasitu Valley, and shortly reached the junction of the Kasitu with the Rikuru, which comes from the west through a wild and mountainous country. The valley of the Rikuru north of the junction is called Ntanta, and is exceedingly fertile; the elevation is about 3,700 feet, and the climate is cool and pleasant. Here Mr. Stewart noticed an important change in the geological formation, the granite and quartz giving place to soft shale and clay schists; and he is of opinion that the Kasitu forms the geological boundary, and that it runs in the trough of some great fault or nonconformity in the formation. Ten miles further north regularly stratified beds of hard, dark grey sandstone were met with. The Rikuru Valley, which Mr. Stewart thought would have taken him gradually down to the lake-level, is at its north end blocked by hills forming the lake coast, and the river flows through winding precipitous valleys, falling 2,000 feet in the last fifteen miles. The water enters the gorge clear and sparkling, and leaves it heavily laden with bluish clay silt, which is visible far into the lake. Mr. Stewart reached the lake at the mouth of this river in S. lat. 10° 45′ 15″. Marching northwards, he visited Mount Waller, which he examined thoroughly, and then, after keeping inland for four days, arrived at the Kambwe lagoon, his starting-point for Lake Tanganyika. The country from Mount Waller to this place is very poor, consisting of swamp and hard clay plain, broken here and there by dry gravel ridges, and occupied chiefly by large game.

THE International African Association have just issued the third part of their periodical publication, which contains extracts from the reports of their travellers in East Africa. M. Cambier gives an account of recent earthquakes on Lake Tanganyika and some details of the work at the station at Karema, the position of which he has fixed as in S. lat. 6° 47′ 50″. M. Popelin narrates the particulars of his journey from Tabora to Karema, and some of the plans for the future. There are also other letters from them, as well as from Mr. Carter and M. van den Heuvel and a medical report by Dr. Dutrieux. M. Burdo, the leader of the third expedition, announces his arrival at Mpwapwa on February 18, and sends a report on the route followed from Saadani. His caravan consists of 108 persons and fourteen asses.

THE German branch of the International African Society intends establishing the first German station at the southern extremity of Lake Tanganyika. The expedition, in which Capt. Schöller, the well-known zoologist, Herr Boehm, and Dr. Kaiser take part, has already left Berlin. Dr. Nachtigal made several communications on the subject at the last meeting of the Berlin Geographical Society.

NEWS has been received concerning the expedition of Dr. Mook and Herr von Holzhausen to the Pettit and Atbara rivers. The travellers left Kassala on January 9, and reached Tomat on the 16th, after crossing the Pettit and the Atbara. Tomat is the winter camp of the Sheikh of Dabanya bedouins. Here they were detained for eight days. Then they proceeded along the left bank of the Atbara as far as the mouth of the Bacher Salam River, but were then compelled to return on account of the absolute uncertainty of the country, and the indisposition of Herr von Holzhausen. The country near the Bacher Salam is completely deserted on account of hordes of Abyssinian brigands.

The travellers were robbed, and owe their lives simply to forced night-marches, gun in hand. They reached Kassala on February 12. Dr. Mook gives a sad account of the deplorable condition of the Soudan, where, as it seems, complete anarchy prevails.

THE United States Government is fitting out an expedition at San Francisco to search for the Arctic exploring vessel *Jeannette*, which has now been some months out. The revenue cutter *Corwin* has been selected for the duty, and she will start with one year's provisions. Her instructions are to search for two missing whalers also. The *Jeannette* went by what is called the eastern passage by Behring's Straits, and Capt. Markham, formerly of Her Majesty's ship *Alert*, of Polar fame, suggested that every year during the *Jeannette's* absence a vessel like the *Corwin* should be sent into the Arctic regions to save her or to learn, as the case may be, of her progress.

AN Austrian expedition, under the guidance of Dr. Otto Benndorf, Professor of Classical Archæology at the Vienna University, is about to start for Olympia. Besides Dr. Benndorf, Prof. E. Petersen (Prague), Dr. W. Gurlitt (Graz), some other member of the Vienna University, and an architect, will take part in the expedition. Dr. Wilhelm Klein, who has already started for Greece, will meet the expedition at Olympia. Another authority in archæology, Prof. Ernst Curtius, has also started for Olympia.

THE Dutch ship *Willem Barends* is being equipped for a third North Polar Expedition.

HERR ROBERT VON SCHLAGINTWEIT, the well-known traveller, has arrived at New York, whence he will proceed to Washington. He then intends to go on a scientific tour to the West of North America.

THE first sheet of a large prehistoric map of Bavaria, by Prof. H. Ohlenschlager, has recently been published. It comprises the district where, in the present day, Munich, Rosenheim, and Kempten are situated. The whole map will consist of fifteen sheets.

NO. 4 of Band xxiii. of the *Mittheilungen* of the Vienna Geographical Society contains the first part of an account of a botanical excursion to the Kasbeck (Caucasus) in the summer of 1871, by Peter Muromtzoff. At the monthly meeting of the Society, on April 27, a letter was read from Dr. Oskar Lenz from Tarudent, describing his passage of the Moroccan Atlas, in which he gives some interesting observations on the mountains and the people. Another letter was from Lieut. Kreitner, who accompanied Count Széchenyi in his attempt to penetrate Tibet through China. Lieut Kreitner states that he plotted carefully the whole route of the party and took many observations, while his companion, Herr von Loczy, took as careful note of the geological features of the region traversed.

L'Exploration for May 13 has the second of a series of articles on Central Japan, Yeddo being the subject of the present instalment; there is also a translation of Lieut. Bove's project of Antarctic exploration, the main points of which we have already given; the number also contains reports of the geographical societies of Quebec and the Argentine Republic, and numerous notes and news, the sources of which, we regret to see, are seldom acknowledged, their value thereby being much decreased. Under the editorship of M. Tournafond this journal is improving, though we think there is still much to be done ere it can be regarded as occupying a first place among geographical journals.

DR. HOLUB, the well-known African traveller, has opened an interesting exhibition at Vienna, which contains thousands of objects brought by him from the South African tribes. They are arranged in various groups, and are classified as zoological, botanical, mineralogical, archæological, ethnographical, and commercial objects.

THE PARALLEL ROADS OF LOCHABER—THE PROBLEM AND ITS VARIOUS SOLUTIONS[1]

AT a recent meeting of the Inverness Scientific Society and Field Club, and again at Fort William, in the immediate neighbourhood of the phenomena, a lecture was given on the above subject by Mr. William Jolly, H.M. Inspector of Schools, who has, for more than ten years, devoted great attention to the subject, and will shortly publish the results of his investigations.

Mr. Jolly thought the subject peculiarly appropriate for their Society, both on account of its intrinsic interest and the eminent men who had written of it, and the proximity of the Club to the locality exhibiting these singular and attractive phenomena. His aim was to state the problem, to explain the solutions offered, give its bibliography, criticise the theories, and develop more fully the one he adopted. He first described the locality of the roads in Glen Roy, Glen Spean, Glen Gluoy, and Glen Laggan, all at the south end of the Great Glen; and their unique and striking aspect, such as to draw the attention of the primitive Celts. They had received several names, being known in Gaelic as *Na Casan*, literally the feet, hence footpaths, of which Parallel *Roads* was a literal translation. Campbell of Islay's rendering, "The Bends," the Rev. Mr. McGregor, of Inverness, the Gaelic scholar, thought fanciful, and without foundation. They were also variously called "lines," "shelves," &c. The highest recognised is in Glen Gluoy at 1,172 feet, another existing there at 964; the three chief in Glen Roy stand at 1,148, 1,067, and 855; the lowest sweeping round into Glen Spean at the same level. A possible road, discovered by Darwin in 1838, in Glen Laggan, above the Loch Laggan Locks, is 1,300 feet high. Their breadth varies from 40 to 70 feet, giving an average of 60. They slope towards the valley at an angle of from 5 deg. to 30 deg., the hill face being inclined from 25 deg. to 40 deg.

Mr. Jolly then, by means of a printed diagram, which enhanced the clearness of the exposition, explained the Conditions of the problem, all of which must be satisfied by any theory claiming to be the true solution. These conditions were the following:—

I.—THE CONDITIONS OF THE PROBLEM

I.—*The Peculiar Form and Character of the Roads*

1. Their general horizontality and parallelism.
2. Their general equality of width (*a*) in the course of the same line, and (*b*) in relation to each other.
3. Their general continuity.
4. Their stair-like form, as of parallel layers laid successively on each other on the hill-side.
5. Their sloping towards the valley.
6. Their being proportionately narrower where they are steeper.
7. Their general absence where solid rock protrudes, and where the slope is exceptionally flat.
8. The *débris* of the hill above and below the Roads sloping more or less at the angle of repose.

II.—*Their Composition*

9. The absence of rounded, water-worn stones along them, and the general greater or less angularity of these.
10. Their consisting of the same *débris* as the rest of the hill-face, and not of transported matter.
11. The absence of cliffs, caves, and rock-notching, or any deep erosion, along their course.

III.—*Their Distribution*

12. Their sudden endings in all cases, without greater accumulations of *débris* or other indications of the cause of the same.
13. The symmetrical disappearance of the same lines at points opposite each other, in the same and *contiguous* valleys.
14. The outward extension of the roads, according to their lesser altitude.
15. Their occasional disappearance for considerable distances.
16. Their different altitudes in different glens, and the absence of the same lines in neighbouring glens.
17. Their being confined to Glen Roy and neighbourhood.

IV.—*Their Relations*

18. The existence of cols in connection with and slightly lower than each of the main roads.
19. The existence of other lines of a different character, above and below the roads. (Dwelt much on by Chambers.)
20. The existence of much terraced *débris*, below the roads, in the bottoms of the valleys containing them.
21. The relation of the roads to the glaciation of the district and its remains.

II.—THE SOLUTIONS OF THE PROBLEM

Mr. Jolly then expounded, by means of another diagram, the various theories proposed to satisfy these Conditions, and account for the Roads, naming the writers advocating them, with their

[1] By William Jolly, F.R.S.E., H.M. Inspector of Schools, Inverness.

dates, and the various works which they had written. All these are given here in the following table:—

	Theories.	Writers.		Works.
By man—Human.	Fingal	Old inhabitants.		
	Hunting roads of kings ...	Old inhabitants.

III.—The Solutions Examined

After referring to the Traditional theories of Fingal and the Hunting Roads, adopted by Pennant in his remarkable "Tour," published in 1771, he told how Playfair had seen similar appearances exhibited by irrigation works at Brieg, in the Valais, which suggested to him his curious solution.

The Diluvial theory held that they were caused by an immense flood from the Atlantic, through a sinking of the West Coast, rushing impetuously along these valleys. There was no use seriously criticising this theory, though adopted in 1861 by Prof. Rogers, of Glasgow.

The Marine theory had had many able supporters, from its first suggestion by Darwin, in 1839, to Campbell of Islay, so recently as 1877. The greatest exponent of this theory was Robert Chambers, in his "Ancient Sea Margins," published in 1848. He held that these lines were nothing but sea beaches, similar to those found so plentifully all over the country. He contended that other lines in these same glens were of the same kind; but these had been shown by Mr. Jolly, in 1873, to be entirely different in character, outline, and composition, and were probably moraines. Mr. Jolly then traversed the Conditions of the problem laid down on the diagram above, and showed how this theory violated, or failed satisfactorily to account for, Nos. 1, 4, 5, 7, 9, 11, 12, 13, 14, 15, 16, 17, 18, 19, and 21, each of which may be tested by the reader.

The Lacustrine theory would be found not open to the same objections. The great difficulty here was the nature of the dam, or barrier, that confined the waters of the lakes, of which the famous Roads were the successive shores or beaches. This theory was propounded, in 1817, by the far-seeing Macculloch, the eminent geologist, and early delineator of Highland scenery and geology; but he, along with others, had not condescended on the kind of barrier required. Two styles of dam had been contended for, the one of detritus, the other of ice. The Detrital dam, first suggested by Dick-Lauder in 1823, had been adopted by Milne-Home, who accompanied Robert Chambers to the region in 1847, and had written of it then, and twice since, with an amount of observation and detail that were of great and permanent value. These writers held that the lakes were contained by huge banks of *débris*, deposited by the sea and other causes, similar to that existing abundantly in many parts of the country. There was no doubt whatever that a large number of lakes, past and present, had been dammed back by such a barrier in many places; but if the roads were so formed, why were not such remarkable lines (whose character was unique) found elsewhere? Mr. Jolly here examined this theory in detail, in connection with the requisite Conditions, and held that it failed to satisfy many of them. How were these barriers so conveniently deposited at the required points, when the Great Glen, and the other valleys were, according to Milne-Home, filled with similar detritus? In the other lakes adduced by him, the outlets were *over the débris*, gradually wearing it away, while here they existed at the upper ends, flowing over hard rock. The roads ended abruptly on the hill face, with no remains of the asserted barriers, heaped up *at their extremities*, as might be expected, and was almost universal. How were the requisite great accumulations so effectively removed, reaching, as these must have done, to above 1,300 feet? The successive roads were on the same hill-face; so that the damming *débris* must have been wholly removed between the lines at their lower ends, before the new beaches were laid down. Mr. Jolly entered into other difficulties attending this theory, and finally concluded against it.

IV.—The Glacial Theory, as adopted

The Glacial theory was started by Agassiz, the great Swiss, who had been accustomed to the work of glaciers, after a visit paid to Lochaber in company with Buckland, in 1840. It has had the greatest number of adherents, Darwin and Lyell having also given up the Marine theory for it. Its chief exponent was Jamieson of Ellon, in an admirable paper published in 1863. Mr. Jolly, by means of a large survey map, variously coloured, entered into a careful explanation of the glaciation of the region. He held that the roads were produced by lakes dammed back by glacial ice, filling the lower parts of the valleys up to the ends of the roads, and gradually retreating with the ameliorating climate, *at the last stage of the second portion* of the Glacial epoch, immediately before the final disappearance of local glaciers from Scotland. The abundant rolled *débris* at the bottom of these valleys was laid down by former glaciers, and by the sea during the great depression in the *middle* of the Glacial period. He described the peculiar configuration of the Ben Nevis Range, with its parallel system of valleys opening out, on the south, to the close, deep Glen Nevis and its eastern continuation, and, on the north, to the broad Glen Spean and broader Glen More. The peculiarity of Glen Spean was that it would receive not only the abundant ice from the glens opening directly on it on the south, but also the greater part of the ice accumulated in Glen Nevis and its continuation, by the two outlets of Loch Treig and Glen Nevis itself. By this means, and by its special relation to the highest mountains in Scotland, it would receive an unusual supply of ice, equalled by no other valley in the country. This was proved not only by its geographical conformation, but by the superabundant glacial remains in the district, of which Mr. Jolly gave full details. During the first period of greater glaciation, the ice from Loch Treig, after entering Glen Spean, turned east down Loch Laggan, and west down the Spean; while Glen Roy itself was filled with an ice-stream from the same valley, which *moved out at its head, down the Spey*, as shown convincingly by the ice-markings there; and the Great Glen and its side valleys were also swathed in ice. As the climate improved at the *close* of the ice period, the glaciers gradually shrank backwards to their sources in the high Nevis glens, which, from their altitude and neighbourhood to the vapour-feeding Atlantic, would be the last in the country to preserve local glaciers. At that time, from its peculiar relations to these glens, Glen Spean would be filled from its head to the sea with a great ice-stream, resting on the *débris* already deposited by the sea, &c., and moving slowly downwards. This stream, entering the south end of Glen Roy, dammed back a lake there, fed by its tributary torrents, which has left its traces in the roads. As the ice gradually shrank in successive steps, the water subsided and the lake extended, as shown by these

lines. Mr. Jolly here pointed out the position of the successive contractions of the ice required to dam the lake, and described the abundant evidences of this last stage of the glaciers there, in scratchings, carried blocks, boulder clay, &c., and in the splendid horse-shoe moraines of the Treig glacier, lying intact across and along Glen Spean. He held that the lowest road extended up Loch Treig only a short distance, suddenly ceasing there, and not round the whole lake—an additional remarkable proof in favour of a glacier then filling that basin down to the ends of the roads, where a dam was necessary. Similar remarks were made regarding the Glen Gluoy and Glen Laggan parallels.

By means of coloured additions laid over the map, the state of the ice at this period, necessary to fulfil the requisite conditions, was graphically exhibited. Mr. Jolly concluded with an appeal to the Society to study the fascinating problem on the ground itself, so as to help to a final settlement of the much-debated question. Inverness had already done honourable work in connection with it, for the height of the lowest road had been first determined by an Inverness man, Mr. Wm. Paterson, sent there for the purpose in 1847 by Mr. Joseph Mitchell, at the request of Mr. Robert Chambers.

Mr. Horne, of the Geological Survey, Banff, and others, afterwards spoke on the subject, and a cordial vote of thanks was awarded to Mr. Jolly.

The reader may consult with advantage, for the better understanding of the subject, the admirable maps of the district of the Ordnance Survey, both the six- and one-inch, in which the Roads and the related phenomena are accurately and fully laid down; or the special Ordnance selected map of the locality, appended to the paper of Sir Henry James, mentioned above.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The authorities of both Girton and Newnham Colleges have supported the general memorial of 8,500 persons in favour of the admission of women to academical degrees and examinations, by informing the Senate in detail of their past proceedings, the number of their students who have been examined informally, none of whom have failed to attain Tripos standards; and both colleges believe that they will be able to offer sufficient guarantees of stability and good administration, so that the University can admit their students to full academical privileges.

Newnham College has now been fully constituted, with Prof. Cayley as president. Prof. Adams has ably aided the Women's Educational Association during the last seven years as president, and now retires, on the amalgamation of Newnham Hall with it, retaining his place on the Council.

Mr. R. C. Rowe, of Trinity College, is appointed an Examiner in the next Mathematical Tripos, and Mr. A. G. Greenhill Additional Examiner.

Dr. Alexander Dickson has been appointed Regius Professor of Botany in the University of Edinburgh and Keeper of the Royal Botanic Garden of that city in succession to Dr. Balfour, who resigned some time ago.

The new representative Council of Education in France has been completed by the appointment of a number of official members. M. Berthelot has been nominated President by the Ministry. A number of sections and special commissions have been established, amongst which we must direct attention to the Commission for Reforming Secondary Instruction. One of the principal features of the intended reform is to divide secondary instruction into three different courses, so that any pupil leaving the school after having gone through the elementary course might have a general knowledge of the principal subjects which are to be investigated more fully in the other two courses.

The University of the City of Pesth celebrated its hundredth anniversary in presence of the Emperor on the 13th inst.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 4.—On the propagation of electricity through current water in tubes, and allied phenomena, by E. Dorn.—Thermic theory of the galvanic current, by J. L. Hoorweg.—On the cause of excitation of electricity in contact of heterogeneous metals, by F. Exner.—On diffusion of salts in aqueous solution, by J. H. Long.—On the relation between propagation of light and the density of bodies, by H. A. Lorenz.—On Stokes's law, by O. Lubarsch.—On after images of motion, by G. SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 29.—"Measurement of the Actinism of the Sun's Rays and of Daylight." By Dr. R. Angus Smith, F.R.S.

When examining the air of towns and the effect of smoke and fogs, I have often wished for a very simple chemical method of measuring the total light absorbed by these gases, vapours, and floating solids. I do not undervalue the work of others, but I think I have obtained a process promising good results with great simplicity, although I daresay it introduces its own class of difficulties.

1. The fundamental fact is that when iodide of potassium in solution is treated with nitric acid, so small in quantity as to cause no change of colour in dull diffused light, a change takes place when the same mixture is brought into clear light; iodine is set free and the solution becomes yellow.

2. The amount of iodine freed can be titrated with great exactness by the use of hyposulphite, as is well known.

In these two facts lies the whole process: the first is the new part, the second makes the first quantitative, and its use is of course part of the novelty.

3. It is known that strong acid liberates iodine. Weak acid does so after a long time, but the process is hastened by light.

4. Heat even to the boiling point does not act so well as light (experiments being made in sealed tubes to prevent loss of iodine, and with a considerable volume of air).

5. Heat assists the action of light.

6. A solution may be exposed day after day so as to give the accumulated effect of sunlight, in a measurable condition at the end of the time.

7. The solution of iodide of potassium as hitherto obtained is subject to change. An old solution, that is, one nearly a month old, was found more sensitive than a new one in all cases tried.

8. The result of No. 7 is, that a certain allowance may require to be made for this, in those cases where the periods of observation with one solution are long.

9. The amount of allowance to be made for temperature is not made out. It is not certain that any is required in the cases when weak acid is used. The weather has not allowed any combined action of great light and heat, but with heat and light in the rays from an electric light with a parabolic reflector, the action was very rapid.

10. Specimens of experiments (prospective at first). It was found convenient to use a solution of 2 grms. of iodide of potassium, afterwards changed to 1 grm., in 100 of water, and to use half of this for an experiment, *i.e.*, 50 cub. centims. of the solution, which may be called A.

A nitric acid solution having an acidity equal to 1 per cent. of sulphuric anhydride was made; this may be called B. Only very small portions of B were added to A.

Examples in which the decomposition was measured by a solution of hyposulphite of sodium, which may be called solution C = 0·1 grm. per litre of iodine (or as convenient). I shall extract experiments made with B solution 0·8 cub. centim., because it is an intermediate one (·2, ·4, ·8, 1·6, and 3·2 have hitherto been the favourites).

1880.		B sol.		Measure by C solution (hyposulphite).
Mar. 3	Sunshine and cloud alternately	0·8	After 2½ hours	8·1. First colour in 20'.
,, 4	Sunshine	0·8	—	First colour in 30'.
,, 5	Dull all day	0·8	,, 4 ,,	0·9.
,, 8	Sunshine	0·8	,, 2½ ,,	7·5. Colour in 20'.
,, 9	A little sunshine ...	0·8	,, 2½ ,,	4·8.
,, 10	Foggy, with a gleam of sunshine	0·8	,, 6 ,,	1·5.
,, 11	Bright	0.8	,, 2½ ,,	7·2.
,, 12	Dull and wet	0·8	,, 3 ,,	0·6.
,, 13	Dark and dull	0·8	,, 2½ ,,	Faint trace.
,, 15	Changeable	0·8	,, 2½ ,,	1·8.
,, 16	Changeable	0·8	,, 2½ ,,	1·6.
,, 18	Sun through haze ...	0·8	,, 2½ ,,	5·8.
,, 19	Bright	0·8	,, 2½ ,,	11·5.
,, 20	Fog till 11.30	0·8	,, 2½ ,,	3·2.
April 1	Sun and showers ...	0·8	,, 2½ ,,	1·6.

(a) 2½ hours' exposure to not very bright clouds; (b) in dark:—

(a) Temp. 12° C. in light.		(b) Temp. 20° C. in dark.	
Sulphuric acid used, same acidity.	C sol. required.	Sulphuric acid.	C sol. required.
0·4	0·5	0·4	0
0·8	3·9	0·8	0
1·6	4·9	1·6	0
3·2	6·1	3·2	0

11. There seems, therefore, no reason to doubt that this is a true photometric process, with special capacities to be developed in time. I may add that I did obtain better results at the window of my house than at the laboratory at the same time, the latter being nearer the centre of the town; thus the process has done the duty it was intended for, although only once tried for this special purpose. I am looking to it as an agent specially for the examination of climate, but of course it may have many uses. This process does not aim at delicacy, but at accumulation of effect. I have not spoken of a standard; the results are only comparative, but the process may be made to supply its own standard.

12. Since writing the above it appears that by using sulphuric acid some of the fears at first entertained may be avoided, as is shown by the following extract:—

B sol.	C sol. required after 2½ hours' exposure of A to light.	C. sol. required after 50 hours' exposure of A to darkness.
0·2	7·6	0·3
0·5	15·1	0·6
1·0	23·4	0·6
2·0	30·4	0·7
4·0	43·6	0·7
6·0	53·8	1·3

The temperature of the solutions exposed to light = 13° C., kept in darkness = 22° C. The iodine volatilised by heat was found so little that it might be neglected here.

The strength of solutions and the kind of acid to be used may vary. Similar results may be got by using bromide of potassium, but it is less delicate. The surface exposed and other questions require attention.

Mathematical Society, May 13.—C. W. Merrifield, F.R.S., president, in the chair.—The following communications were made:—On Cremonian congruences, by Dr. Hirst, F.R.S.; on some statical and kinematical theorems, by Prof. Minchin; on a class of analytical problems, by Prof. Cayley, F.R.S.

Linnean Society, May 6.—H. T. Stainton, F.R.S., in the chair.—Three Foreign Members were elected.—Mr. T. Christy read a letter from Mr. Blacklaw, of St. Paulo, Brazil, intimating that his experiments to rear the Liberian coffee-plant had all failed, though different seasons, altitudes, and other conditions, without and indoors, had been tried.—The abstract of a paper by Prof. G. Dickie, notes on algæ from the Amazon, was read by the Secretary. This collection was made by Prof. J. W. H. Trail, and consists of 288 species, whereof 190 are diatoms, 31 desmids, and 67 other algæ, 9 of the latter being new forms.—Prof. P. M. Duncan orally communicated the substance of a paper on an unusual form of the genus *Hemipholis*, Agass. This was dredged by Dr. Wallich off the Algulhas Bank, S.W. of the Cape of Good Hope. Its zoological position may be doubtful, for the classification of the Ophiuroidea is at present full of anomalies; but the specimen itself nevertheless possesses unusual interest from the nature of the so-called dental or chewing apparatus. These peculiar dental structures and other points were elucidated by the author.—Mr. G. T. Bettany gave some remarks on the vocabulary of botanical terms in use in the description of flowering plants. The author advocated making a distinction between terms used in elementary descriptions in educational works and those used in the terse and complete floras. Under evolution there was much chance of botanical progress if terms were simplified and made such as children could comprehend; but almost every book aiming at comprehensiveness became obscure. Thinking it necessary to give every possible variety of terms and to add to them, it repelled, instead of aiding in the wide diffusion of knowledge. For these and other reasons the author strongly objected to the now too frequent use of tri- and polysyllabic terms.—Prof. Ray Lankester read a paper on the tusks of the fossil walrus found in the red crag of Suffolk. He withdraws the generic name of *Trichecodon*, instituted by him in 1865, and refers a series of later-discovered large tusks in the Ipswich Museum, as also his formerly-described specimens, to the living genus *Trichechus*, but specifically distinguished in this case as *T. Huxleyi*. He is inclined to think there is insufficient ground for the generic subdivisions *Alachtherium* and *Trichecodon*, as used by Van Beneden, and moreover signifies his opinion that there is yet no good evidence in support of the association of the Suffolk and Antwerp tusks.—A short communication, on an irregular species of *Amblypneustes*, by Mr. Chas. Stewart, was taken as read.

Zoological Society, May 4.—Prof. W. H. Flower, F.R.S., president, in the chair.—Mr. Sclater exhibited a specimen of the Ibis (*Geronticus comatus*), lately obtained at Biledjik, on the Euphrates, by Mr. Danford, and made some remarks on its previously-known distribution.—Dr. A. Günther read a note correcting the statement made by him at the meeting of the Society on January 20 last respecting the occurrence of *Holocanthus tricolor* on the British coast. Further particulars received by Dr. Günther had led him to decide that this fish could not be considered as having been caught on the British coast.—Mr. W. A. Forbes read a note on the cause of death of a leopard in the Society's menagerie.—Mr. Dobson exhibited and made remarks on some bones of the Dodo which had been transmitted from Mauritius in 1847-50 by Dr. F. Reid to Sir James Macgregor, and having been deposited at Fort Pitt, Chatham, were afterwards removed to Netley Museum.—Mr. F. Jeffrey Bell exhibited the immature specimen of *Echinolampas*, referred to by him in his communication on *Palæolampas*, pointing out its more differentiated characters, and suggested the possibility of its being an example of *E. oviformis*.—Prof. Flower called the attention of the meeting to the fact that a young specimen of the Lesser Fin Whale (*Balæonoptera rostrata*), fifteen feet long, which had been taken off the coast of Cornwall, was now being exhibited in London.—A communication was read from Prof. J. O. Westwood, containing an account of the species of Saw-flies composing the Australian genus *Perga* of Leach.—A communication was read from Dr. W. J. Hoffman on a supposed instance of hybridisation between a cat and a lynx.—Mr. W. A. Forbes read the second and third parts of his series of papers on the anatomy of Passerine birds. These communications related to the syrinx and other points in the anatomy of the *Eurylæmidæ*, and to the structure of *Philepitta*, and its position among the Passeres.—A communication was read from Mr. F. Day, in which he gave the description of a new Entomostracon from Afghanistan.—Mr. Oldfield Thomas read a paper on a collection of mammals brought from Ecuador by Mr. Clarence Buckley. Among these was a new species of *Bassaricyon*, proposed to be called *B. alleni*.—Mr. A. G. Butler read a paper containing descriptions of a collection of Lepidoptera made by Major Howland Roberts at Rokeran, near Kandahar, on the River Urgundab.—Mr. G. French Angas read a paper containing further additions to the marine molluscan fauna of South Australia, with descriptions of six new species.—A second paper by Mr. Angas contained the descriptions of three species of marine shells from Port Darwin, Torres Straits, discovered by Mr. W. J. Bednall, and of a new *Helix* from Kangaroo Island, South Australia.

Geological Society, April 28.—Robert Etheridge, F.R.S., president, in the chair.—Rev. James Oliver Bevan, M.A., Arnold Hague, Augustus Constable Maybury, Henry Peter Meaden, William Peregrine Propert, and Francis Randell were elected Fellows of the Society.—The following communications were read:—Description of parts of the skeleton of an anomodont reptile (*Platypodosaurus robustus*, Ow.) from the trias of Graaff Reinet, South Africa, by Prof. Owen, C.B., F.R.S. The author referred to certain triassic reptiles from South Africa, already described by him, as showing certain resemblances to implacental mammals. Another still more interesting indication of such resemblances is furnished by some remains from Graaff Reinet received from Mr. E. J. Dunn. These consist of some thoracic vertebræ with portions of ribs, a sternal bone, a scapula, and a right humerus, found imbedded in one mass of rock, and of a femur and phalanges, and a pelvis in another mass. The author described these bones in detail. The vertebræ were said to agree most nearly with those of *Dicynodon* and *Oudenodon*. The supposed sternal bone is of a rounded hexagonal form, and is regarded by the author as the anterior bone of the sternum proper, which is usually unossified in recent lizards, but well ossified in *Ornithorhynchus*. In the scapula, also, the author pointed out resemblances to that bone in *Ornithorhynchus*. The humerus in its general proportions, and

especially in the great development of its ridges, was also shown to resemble the same bone in the Monotremes. The ungual phalanges were described as broad and obtuse, probably constructed to bear claws adapted for digging, as in *Echidna*; the femur also resembles that of the last-named animal. The author remarked upon these approximations to the *monotrematous* mammalia, in allusion to which he proposed the name of *Platypodosaurus robustus* for this animal, the humerus of which was 10½ inches long and nearly 6 inches broad at the distal end. He also alluded to the interesting problems opened up by the study of these South-African reptiles in connection with their possible relationships to the low implacental mammalia of New Guinea, Australia, and Tasmania.—Note on the occurrence of a new species of *Iguanodon* in the Kimmeridge clay at Cumnor Hurst, three miles west of Oxford, by Prof. J. Prestwich, F.R.S. The pit in which the occurrence of *Iguanodon* was discovered was worked in Kimmeridge clay at the foot of an outlying mass of Lower Greensand forming an isolated hill. The Portland beds, which occur at Shotover, are here wanting. The bones were found in a thin sandy seam intercalated in the clay, and traversing the hill at least fifteen feet below the greensand. The skeleton was probably almost entire; but, as attention was not directed to it until nearly all the clay had been removed, many bones were lost and others injured. Several vertebræ of *Ichthyosaurus* were found in the same seam, and the characteristic *Gryphæa virgula* occurred in profusion. The clay above and below contained fossils of Kimmeridge types. The author stated his opinion that land probably lay to the south-west of the Oxford district.—On *Iguanodon prestwichii*, a new species from the Kimmeridge clay, by J. W. Hulke, F.R.S. In this paper the author described in detail the remains of *Iguanodon* found at Cumnor Hurst in the Kimmeridge clay, as described in the preceding paper. They illustrated nearly every part of the skeleton of an immature individual, adding greatly to our knowledge of the variation of the vertebræ in the several regions of the vertebral column, and of the structure of the head and hind limbs. In the latter both the tibia and the fibula articulate (as in embryo birds) with the *os calcis*, which bone is now first identified in *Iguanodon*. The sacral vertebræ were only four in number, and the species further differed from the Wealden *Iguanodon mantelli* in the simpler character of the serration of the teeth, of which the lamellæ are not mammillated, and in having the vertebræ of the trunk and sacrum not so compressed. The author named the species *Iguanodon prestwichii*.

Institution of Civil Engineers, May 11.—Mr. W. H. Barlow, F.R.S., president, in the chair.—On the manufacture and testing of Portland cement, by Major-General H. Y. D. Scott, F.R.S., and Mr. Gilbert R. Redgrave.—On Portland cement concrete, and some of its applications, by Mr. E. A. Bernays.—On Portland cement: its nature, tests, and uses, by Mr. John Grant.

Anthropological Institute, May 11.—A. L. Lewis in the chair.—The following papers were read:—Notes on prehistoric discoveries in Central Russia, by C. H. E. Carmichael, M.A.—Notes on the occurrence of stone implements of the surface-period in South Russia, by W. D. Gooch.—Notes on the Western Regions, by A. Wylie.—On jade implements in Switzerland, by Hodder M. Westropp.—Flint implements from the Valley of the Banu, by W. J. Knowles.

PARIS

Academy of Sciences, May 10.—M. Edm. Becquerel in the chair.—The following papers were read:—On the transcendants which play a fundamental part in the theory of planetary perturbations, by M. Tisserand.—On a proposition of the theory of elliptic functions, by M. Hermite.—On a rain of dust observed from April 21 to 25, 1880, in the departments of Basses-Alpes, Isère, and Ain, by M. Daubrée. This dust gave a reddish tinge to snow on the mountains at Barcelonnette, up to 2,800 and 3,000 m. (snow further up remaining white). Its chief mineralogical characters were: effervescence with acids, mixture of hydrated peroxide of iron, presence of spangles of mica, residue of fusible acids, principally feldspathic. The dust is thought to be of terrestrial origin, but not volcanic, nor Saharan. (Somewhat similar showers fell in France in October, 1846, and May, 1863.) The same phenomenon seems (from another note) to have been experienced at Autun (Saône-et-Loire) on April 15, *i.e.*, ten days before.—On the crystalline form of magnesium, by M. Des Cloizeaux. Having examined the fine magnesium crystals lately obtained by M. Dumas, he finds that among the rhombohedric metals magnesium is that which, after zinc, presents the most acute primitive rhombohedron. The crystals in question are very malleable and sectile; no cleavage was observed.—On a Cicadella (*Hysteropterum apterum*) which attacks the vines in the department of the Gironde, by M. Blanchard.—On the law of reciprocity in the theory of numbers, by Prof. Sylvester.—On the new siphon established over the Canal Saint Martin, and on the works of sanitation of the Bercy quarter, by M. Levy. The sewers of Bercy (which formerly discharged into the Seine) are in some parts lower than the collector designed for them, and had to cross the Canal Saint Martin to reach this. An ingenious system of siphons and trompes was devised to meet the difficulty.—On linear functions, by M. Pellet.—Experimental researches on the decomposition of some explosives; analysis of products, by MM. Sarrau and Vieille. This related to decomposition of explosives under a pressure near the atmospheric. In this case all the explosives liberate bioxide of nitrogen and carbonic oxide. It is important, then, in mining operations to avoid with all care failure of detonation.—On the determination of algebraic integrals of algebraic differentials, by M. Zeuthen.—On simultaneous linear equations and on a class of non-plane curves, by M. Picard.—On a class of functions of two independent variables, by M. Picard.—On the theory of phenomena of interference where rotatory polarisation intervenes, by M. Gouy. He takes a point of view of interference phenomena different from that of Fresnel, and superior in simplicity.—On the equipotential lines of a plane formed of two halves unequally conductive, by M. Guébhard.—On the mutual actions of magnetic needles plunged in liquids, by M. Obalski. Two magnetic needles are hung opposite each other (and a little beyond the range of attraction) by two unlike poles from very fine threads over water in a vessel, which water can be raised gradually over them (by means of a connected tube of caoutchouc). When immersion begins, the needles draw near each other by their immersed parts, and when the immersion has reached the third or fourth of the needles' length, they go together. This is probably due to the separating force of gravity being weakened by immersion.—Analysis by the graphic method of movements produced by excitations of the brain, by MM. François Franck and Pitres. To the detached tendon of a limb-muscle they attached the transmitting myograph; an electro-magnetic signal (of M. Deprez) registered the time on the drum, and another signal the excitation. The character of movements caused by various electrical excitations is described. As to retardation of the movement on the instant of cortical excitation, this is found constant for a given muscular group in the same animal, whatever the form or intensity of the electric excitant. A notable part of it is due to physiological resistance of the grey cortical substance. Beyond a certain intensity of stimulation movements are produced on the same side of the body as the part of brain stimulated, as well as on the opposite, and the retardation for these movements is greater. The retardation is greater for hind than for fore limbs.—On a rain of dust at Autun, by M. De Jussieu (see above).—M. De Lesseps presented specimens of silver ore from California, and gave some information about Mr. Mackay's mines at Virginia City, the galleries of which have been pushed about 1,000 metres, a depth hardly exceeded in Europe (Bohemia). Descent is by means of hydraulic motors.

MATHEMATICAL JOURNALS

American Journal of Mathematics, Pure and Applied. Published under the auspices of the Johns Hopkins University. Vols. i., ii. (Baltimore: John Murphy and Co.)

THE *American Journal of Mathematics* has now completed its second volume, and has obtained an established place among the leading mathematical journals. Thanks to the Johns Hopkins University at Baltimore, America possesses, what has never been attempted in England, a *quarto* journal entirely devoted to mathematics.

Perhaps in no branch of science is the literature of the subject so exclusively confined to periodical publications as in mathematics. The books that are written are merely text-books and, in this country, generally have reference to certain special examinations. Of course there are exceptions which will immediately occur to mathematicians, such as Salmon's treatises and Todhunter's histories, and the exceptions are more numerous in Germany; but, even when all the books published in all languages which are above the rank of school-books are included, they bear an extremely insignificant proportion to the amount of original mathematical literature contained in periodical publications; in fact it would be impossible to form any idea of the present state and extent of mathematical science from any study of the books upon the subject. The same is to some extent true of all branches of science; but the want of treatises is greatest in mathematics on account of the smallness of the audience addressed and the impossibility of expressing even the results in a manner intelligible to the non-mathematical reader.

As a consequence of the scarcity of treatises there are many extensive branches of mathematics (such as, for example, the Partition of Numbers) which exist only in the periodicals; and the contents of the latter are therefore less transitory, so to speak, than in other sciences, *i.e.*, the papers are less liable to be superseded by subsequent writings and to become only of historical interest.

A journal devoted to a special subject always promotes activity in that subject, as one paper gives rise to another; but, besides this, it collects in one place many researches which would otherwise be widely scattered in the publications of different societies; and this latter advantage is much more apparent when, as in the case of the *American Journal*, its extent is sufficient to enable it to receive elaborate memoirs. Thus M. Lucas' "Théorie des Fonctions simplement périodiques" occupies 90 pages, and Mr. McClintock's "Essay on the Calculus of Enlargement" 61 pages. There is no reason to suppose that the majority of the papers contained in the *American Journal* would not have been written and printed, if the latter had not existed, but it is a real gain to the mathematician to have them all united in a single periodical.

The great increase in the number of mathematical journals in the last few years is very remarkable. The following is, we believe, a complete list of all the journals now in existence which are exclusively devoted to mathematics, with place of publication and date of foundation. An asterisk denotes that the journal to which it is prefixed admits problems for solution:—

AMERICA	
**Analyst*	[Des Moines, 1874], 8vo.
American Journal... ...	[Baltimore, 1878], 4to.
ENGLAND	
Quarterly Journal... ...	[Cambridge, 1839], 8vo.
Messenger	[Cambridge, 1862], 8vo.
FRANCE	
Journal (*Liouville*) ...	[Paris, 1836], 4to.
**Nouvelles Annales* ...	[Paris, 1842], 8vo.
Bulletin	[Paris, 1870], 8vo.
GERMANY	
Journal (*Crelle*)	[Berlin, 1826], 4to.
Archiv (*Grunert*)... ...	[Greifswald, 1841], 8vo.
Zeitschrift (*Schlömilch*)..	[Leipzig, 1856], 8vo.
Annalen (*Clebsch*)... ...	[Leipzig, 1869], 8vo.
Fortschritte	[Berlin, 1871], 8vo.
Repertorium	[Leipzig, 1877], 8vo.
ITALY	
Annali (*Tortolini*) ...	[Rome, 1850], 4to.
Giornale (*Battaglini*) ...	[Naples, 1863], 8vo.
Bulletino (*Boncompagni*).	[Rome, 1868], 4to.
BELGIUM	
**Nouvelle Correspondance*.	[Mons, 1874], 8vo.
HOLLAND	
Nieuw Archief	[Amsterdam, 1878], 8vo.
DENMARK	
**Tidsskrift*	[Copenhagen, 1859], 8vo.

To these may be added the **Reprint* [London, 1864] from the *Educational Times*, consisting almost entirely of problems and solutions; and also, although not strictly journals, the *Proceedings* of the London Mathematical Society [London, 1865] and the *Bulletin* of the French Mathematical Society [Paris, 1872]. The object of two of the journals, the *Fortschritte* and the *Repertorium*, is to give *résumés* of papers published elsewhere. It may be observed that all the journals included in the above list are strictly mathematical, although in the titles of some of them mathematics is coupled with physics or astronomy. A few minor periodicals, appearing at long intervals, have been omitted.

Thus of the nineteen journals included in the above list no less than seven have been founded in the last ten years, while four were founded in the preceding decade, 1860-70, so that only eight date from farther back than 1860. The oldest and by far the most celebrated journal is *Crelle*, which has now reached its eighty-ninth volume: many of the most important mathematical discoveries of the present century are contained in its pages.

The publication of problems and solutions in a mathematical journal is always to be regretted, as it is impossible not to feel that the space might be better occupied, and that the presence of mere exercises in a periodical which should be devoted to the advance of the science is undesirable. Their insertion in several cases is doubtless due to a wish to increase the number of readers by including a class who would take but little interest in, or be unable to follow, original mathematical researches; but the "problem for solution" may even be defended on scientific grounds, as it is a well-known historical fact that not a few of the greatest mathematicians were first led

to take a strong interest in mathematics by being tempted in their younger days to attack such questions. It may be remarked also that the mathematical problem has itself undergone great improvement since the days of the *Ladies' Diary*, when the problems usually appeared by the side of the enigmas, charades, &c. These problems were generally merely made-up exercises or puzzles—such as are to be found now only in examination papers—in which the data were wholly fictitious or even ridiculous; the modern problem, especially in pure mathematics, is often a theorem, or a particular case of a theorem, of very considerable intrinsic interest. It is right to mention that the *Nouvelles Annales* is really intended mainly for purposes of instruction, and that apparently a Continental student derives from this publication very much the same kind of practice and skill in the treatment of problems which at Cambridge he would obtain from his private tutor.

The history of mathematical journalism in all countries seems very similar: first, there is the Annual or other periodical, containing at the end puzzles, problems for solution, &c., the best solutions and the names of those who sent in correct solutions being given in the following number; at length these are supplemented by short articles on particular subjects—frequently suggested by the problems—by the leading contributors. The next step is the mathematical journal, consisting of two parts, the one containing original papers, and the other—quite distinct—containing a limited number of problems and solutions. Finally we have the strictly scientific journal, differing in no essential respect from the *Transactions* of a society; and, it is scarcely necessary to remark that, on account of the length of many of the formulæ, a quarto journal is preferable to one of octavo size.

From an interesting account of American mathematical periodicals by Mr. David S. Hart, which was published in the *Analyst* for September, 1875, it appears that the first mathematical journal published in America was the *Mathematical Correspondent*, which was issued at New York on May 1, 1804, and of which eight quarterly numbers only were published. The next periodical was the *Analyst, or Mathematical Museum*, of which the first number was published in 1808; five numbers only appeared. In January, 1825, the first number was issued of the *Mathematical Diary*, which continued till March, 1832; for the first two years it was published quarterly, and for the remaining five years annually, thirteen numbers in all being issued; this journal, Mr. Hart remarks, "contained besides solutions of problems many important and valuable essays on the various branches of exact science, and was the best mathematical serial that had as yet appeared." The next periodical was the *Mathematical Miscellany*, which lasted from 1836 to 1839; it had a junior and senior department, the former for young students and the latter for mathematicians; eight numbers were issued. In 1842 the first number appeared of the *Cambridge Miscellany of Mathematics, Physics, and Astronomy*, edited by Professors Benjamin Peirce and Joseph Lovering, but only four quarterly numbers were issued.

In October, 1858, Mr. J. D. Runkle published the first number of the *Mathematical Monthly*, which is by far the best known of the journals which appeared previously to those now in existence; it contained papers not exceeding eight pages in length, notes and queries, and five problems in each number intended for students, with solutions in a subsequent number. This journal, which seemed to be filling a want, unfortunately had to be discontinued in 1861 in consequence of the war. No further attempt was made to establish a mathematical journal till January, 1874, when Dr. J. E. Hendricks established the *Analyst*, which for the first year was issued monthly and has since appeared bi-monthly. This journal, in spite of many serious disadvantages due to difficulties of printing, &c., has done good service to mathematics in America. It is not to be compared to the *American Journal* as regards the importance of its papers, and a considerable portion of each number is devoted to problems; but the editor may fairly claim to have done for the encouragement of the science not less than have the editors of the *Journal*, to which the *Analyst* may now be regarded as a valuable supplement.

Soon after the foundation of the Johns Hopkins University, the *American Journal* was issued (in 1878) under its auspices, with Prof. Sylvester as chief editor and Mr. W. E. Story as acting editor, assisted by Professors Benjamin Peirce, Simon Newcomb, and H. A. Rowland. The contents of the journal have been worthy of the reputation of the editors, and as regards printing, &c., there is nothing to be desired. Among the papers may be noticed, besides the numerous and important investigations of Prof. Sylvester himself, those by Mr. G. W. Hill on the lunar theory, by Mr. G. B. Halstead on the bibliography of hyperspace and non-Euclidean geometry, and by Mr. Story on the elastic potential of a crystal. There are also contributions from Prof. Newcomb, Prof. W. W. Johnson, Mr. C. S. Peirce, &c., and from European mathematicians, Professors Cayley, Clifford, Lipschitz, &c.

It will be generally admitted that Prof. Sylvester's researches are amongst the most valuable contained in the *Journal*; one of the most elaborate of these, which occupies 60 pages, relates to an application of the new atomic theory to the graphical representation of the invariants and covariants of binary quantics. Most of the others also have reference to invariants or covariants or cognate branches of the modern higher algebra, and the great amount of space devoted to this important subject is very noticeable. There is a paper by Prof. Cayley on the calculation of the minimum numerical generating function of the binary seventhic, and Prof. Sylvester is now publishing his valuable tables of the generating functions and groundforms for binary quantics and systems of binary quantics, which he has calculated with the assistance of his pupil, Mr. F. Franklin.

There are other well-known American mathematicians, Asaph Hall, Artemas Martin, E. B. Seitz, C. H. Kummell, &c., who do not as yet appear to have contributed to the *Journal*, although their names are familiar to readers of the *Analyst*, and when these are added to the already considerable number of American authors of papers in the *Journal*, it is clear that the mathematicians in America are sufficiently numerous to support permanently such a journal as that over which Prof. Sylvester presides. The *American Journal* has started well, and there is no reason to suppose that it has not as great a

future before it as awaited *Crelle's Journal* half a century ago.

The only method of "endowing the research" of the pure mathematician is to give him a journal, and this the Johns Hopkins University has done for America. Two years ago it seemed a question whether it was worth while to apply to the Cambridge Commissioners to endow mathematics in a similar manner in England. On the whole it seemed better not to make such an application, as the obvious difficulties in the way of the editorship, &c., of a subsidised journal would be considerable, and the existing journals, which support themselves, seem to fairly meet the demand. But for the foundation of the London Mathematical Society in 1865 the want of a large mathematical journal would have become pressing; as it is, the *Proceedings* of this Society may now be regarded as taking the place of a leading English journal. The journal, however, has two important advantages over the publications of a society: (1) the printing of the papers is unaccompanied by the formalities of reading, being reported on by referees, &c.; (2) the journal is much the more procurable, especially if separate numbers be required; it also affords more rapid publication.

J. W. L. GLAISHER

OUR BOOK SHELF

Six Life Studies of Famous Women. By M. Betham Edwards. (London: Griffith and Farran, 1880.)

THIS is a readable and instructive collection of studies, containing, among others, notices of two women notable in their different ways in the history of science—Caroline Herschel and Alexandrine Tinné, the famous African explorer. The studies are marked by care and neatness, and are on the whole fair estimates of the work and life of the subjects. They are accompanied by six well-executed steel portraits.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Lord Rosse's Telescope.

IN an article in the *Times* newspaper there occurs the passage—"With regard to the mighty mirror of the Parsonstown reflector M. Struve has spoken in no very complimentary terms. It was said of Sir W. Herschel's four-feet reflector that it 'bunched a star into a cocked hat;' but even this is scarcely less satisfactory than M. Struve's remark that at Parsonstown 'they showed me something which they said was Saturn, and I believed them.'" This revival of the statement attributed by Mr. Proctor in *Frazer's Magazine* for December, 1869, to "a distinguishing (*sic*) astronomer," has called forth the appended letter from the Imperial Astronomer of Russia. It is satisfactory to receive direct from M. Struve a statement of his experience of the performance of the six-foot instrument.

ROSSE

25, Chesham Place, S.W., May 26, 1880.

"MY DEAR LORD ROSSE,—Yesterday evening a friend conveyed to me a note, inserted in the *Times* of April 3, under the title 'Three Giant Telescopes,' in which I am told of having expressed myself in a very uncourteous manner on the optical qualities of the great reflector constructed by your late father. I beg leave to say that those expressions are altogether invented by the anonymous author of the note, or, at least, quite a voluntary and thoroughly wrong interpretation of what I may have said. I am sorry my name is abused in such a manner by people who probably have a design of their own in depreciating the performances of the instrument, the construction of which marked in itself a high progress in optics and mechanics, and which in its space-penetrating power has not had any rival until now, though certainly with regard to definition (particulary when the mirror is considerably out of horizontal position) there are other instruments superior to it.

Brain Dynamics

IN his clearly-written letter on this subject Mr. Tolver Preston seems to think that the reconciliation which he offers between Free Will and Necessity is a novel one. In this, however, he is mistaken, as the supposed reconciliation was very distinctly stated by the late Prof. Clifford in his lecture at St. George's Hall on "Body and Mind." But of more importance than the novelty of the reconciliation is the question as to its validity, and it is on this question that I shall make a few remarks.

The suggested reconciliation is as follows:—No upholder of Free Will can desire to maintain that a man may act, or desire and will to act, otherwise than in conformity with his character; for to maintain this would be to maintain that a man may act at random, without reference to any fixed principles of action, and that the Will is free only in the sense of being erratic. But if it is admitted that by freedom of the Will is meant freedom to choose within the lines laid down by previous character, and freedom, therefore, to shape future character by present volitions, it follows that upholders of the Free Will doctrine ought not to quarrel with those who uphold the doctrine of Necessity as due to "brain dynamics."; for the latter doctrine supplies the very basis which the former doctrine requires. It shows *why* the Will always acts in accordance with previous character; it shows that the Will can never be free in the sense of being lawless, or not determined by adequate causes; and it shows that the Will must be free in the sense of being able to choose between motives supplied by the structure of preformed character. Thus, it is represented, believers in Free Will ought to welcome modern physiology with all its "materialistic" deductions from "brain dynamics" to mental changes. For, unless these persons desire to land themselves in that quagmire of hopeless nonsense—the conclusion that volitions are uncaused —they have no alternative but to conclude that volitions are determined by motives, which are themselves determined by previous character. But if once volitions are thus conceded to enter the stream of causation, the more rigid the causation, the better for such freedom as remains, seeing that the latter, if always strictly determined, can never be lawless or erratic. Now of all things rigid, that which is least open to any suspicion of laxity is physical causation. Consequently, if the Determinism of Psychology admits of being resolved into the Neurility of Physiology, believers in the Freedom of the Will ought to rest peacefully satisfied that while they are free to act within the limits prescribed by their own characters, they have the sure and certain guarantee of physical causation that their volitions can never break out into activity at random. Or, as Mr. Tolver Preston puts it: "Solely in virtue of the fact that there is strict Causal Sequence in nature are the actions brought into strict conformity with individual brain structures (or with character). If the principles of dynamics were not rigid, or if the laws of nature were liable to alteration, a man's actions might sometimes be in harmony with his brain structure [character], sometimes in discord with it; or any number of persons, though possessing totally different brain-structures [characters], might act identically. The questionable expediency of the proceedings of those who are disposed to grumble at what they term the 'iron' laws of nature becomes apparent here."

Such, I think, is a full statement of the suggested reconciliation. I shall now proceed to show that as a reconciliation it is utterly futile.

There is nothing to be said against the reasoning as far as it goes; but it is curious, if not unsatisfactory, that both Prof. Clifford and Mr. Preston should have performed their little play without letting us know that the Prince of Denmark has been omitted. His name in this case is Responsibility. No doubt it is perfectly true that the suggested reconciliation shows to all believers in Free Will that their belief ought only to include freedom "as freedom to act in accordance with" character;

that "such freedom actually exists;" and that "the very condition for its existence is seen to be the prevalence of that strict causal sequence in nature demanded by the Necessitarians." But although the suggested reconciliation shows all this, it fails to extend to the upholders of Free Will the relief which they most require, for the procuring of which their doctrine was conceived, and for the continuance of which their doctrine is continued, notwithstanding the manifest and manifold absurdities which it involves. That the supposed reconciliation here fails, seems almost too obvious to require showing. The more certainly it can be proved that every volition is the result of definite causes, and therefore that the character—even in that part of it which is formed by all previous volitions—is also the result of definite causes, the less possibility is there of justifying the sense of Responsibility.

Unless it can be shown that a man is responsible for the character of his character it is nonsense to speak of him as responsible for his actions, when these are determined by his volitions, which, in turn, are determined by his character. Can it, then, be shown that a man is responsible for the character of his character? Obviously not, either upon Clifford's view or any other. It is futile to speak of a man as "the architect of his own character"; for, according to the hypothesis before us, he is nothing of the kind: his character has been built up stage by stage, first by hereditary transmission, next by numberless unintentional influences acting both from within and from without, and lastly by numberless acts of volition, every one of which was strictly determined by causes, and therefore was what it was by way of inevitable necessity. It follows, therefore, that the supposed reconciliation between Free Will and Necessity tends rather to emphasise than to diminish the difficulty; it shows more clearly than ever that the sense of Responsibility, and the correlative sense of Praise or Blame, are alike incapable of any logical justification. No doubt the sense of Responsibility, the love of Praise, and the dread of Blame act as powerful motives to volition; but this fact clearly does not justify either the feeling of responsibility in him who acts, or the feeling of approval or disapproval in him who observes.

But it is of importance also to see that it is quite as impossible to justify these feelings by the doctrine of Free Will as it is by the doctrine of Necessity. For if volitions are uncaused, or but partly and irregularly caused, it is clear that neither moral responsibility, nor praise, nor blame can attach to the unfortunate man whose actions are not guided even by the hand of Providence, but occur by way of inexplicable caprice.

What, then, it cannot but be asked, is the psychological explanation of these deeply-rooted feelings of Responsibility, Praise, and Blame, which can never be eradicated by any evidence of their irrationality? To me it appears the only answer is that these feelings have been gradually formed as instincts, which, while undoubtedly of much benefit to the race, are destitute of any rational justification. GEORGE J. ROMANES

The Inevitable Test for Aurora

IN NATURE, vol. xxii. p. 33, is an implication, if not also a declaration, that the limits of height in the atmosphere, at which the *Aurora Borealis* both can, and cannot, appear, have been ascertained by those world-respected scientists, Messrs. Warren De La Rue and Hugo W. Müller, F.R.S.S. both. The skill of their experiments, the sufficiency of their exhausting apparatus, and the power of their unequalled chloride of silver battery are beyond all question; and they did, without doubt, ascertain in a very complete manner at what particular degrees of rarefaction of certain glass vessels, their electric discharges therein, took such and such appearances.

But what proof do they give that those appearances were aurora?

They mention carmine-coloured discharges in the denser air, salmon-coloured in more rarefied, and pale milky white in the highest rarefaction of all. But those colours, as judged of merely by the eye, are little proof in themselves of the presence of one and one only out of a number, of different things, elements, or manifestations somewhat similarly coloured. So that although I would not presume to be too confident of the sufficiency of the test I am about to set before those eminent men, still, as I was obliged to have the honour of presenting it to that admirable electric philosopher, M. Gaston de Planté, of Paris, three years ago, when he described with his equally wondrous collection of "secondary" galvanic-battery pots and currents of terrific intensity, the *aurora-like* effects it produced—impartial justice demands the same test to be presented now to our best physicists on the west of the British Channel.

Now the test is simply this: did the F.R.S.S. gentlemen see in their electric lights the late M. Ångström's one citron line of aurora?—that line being so invaluable an indication of aurora's presence, though hitherto uninterpreted (see Rand Capron's laborious book of Auroræ[1]); and without which strange linear hieroglyph written from Creation most legibly on its forehead, no aurora has ever yet been seen by mortal man properly equipped for the occasion. And, inasmuch as the learned F.R.S.S. speak of so many variations of red—as carmine, rose, and salmon colours of various kinds—while I had the opportunity of calling attention in NATURE in 1872 to the remarkable fact that *maugre* all the violent variations of auroral red to the eye on that occasion, there was only one and the same red line in the spectroscope through every one of them—did the London scientists see that unique red auroral line manifesting itself through all their various artificial reddish tints; or, had each tint a line or lines peculiar to itself; or was there no red line whatever to be seen, though they looked for it never so earnestly; or is that crucial part of their experiment described elsewhere than in NATURE, vol. xxii. p. 33? PIAZZI SMYTH

15, Royal Terrace, Edinburgh, May 17

Variability of 60 Cancri

I FOUND the above to be a red star in 1874, and the Rev. Mr. Webb, in the same year, made independently a similar observation. It appeared to me of 8 magnitude, as it did also to Mr. Webb. It is numbered 212 in my *Red Star Catalogue*, where, considering Argelander's previous estimate of about 6 mag., I remarked that it might be variable. This appears now certain, as on April 27 of the present year, and again on May 17, I found the star to be 5 mag. and red-orange in colour. Dr. Copeland, of Dunecht, replying to a letter on the subject, informs me that on referring to various authorities, he finds estimates of the star's magnitude from 5 by Lalande to 7 by Bessel, and in W. B. it is marked 8. As I have seen it in both extremes, the recorded differences cannot be ascribed to inaccuracies in different observers, and I must regard the star as a remarkable variable well worth special notice. It is now passing away from us, but I saw it so late as May 17 in very bright twilight, and its proximity to *Alpha* gives facilities for estimations of colour and magnitude.

Millbrook, Tuam, May 21 JOHN BIRMINGHAM

Notes of the Cuckoo

I REMARK that all the cuckoos here intone in a minor key, except one, who alone does not flatten the 3rd of the tonic. The key is in all cases precisely D of concert pitch, as proved by a tuning-fork, and the first note is F on the fifth line. In quality of voice *the Major* is not equal to the others, while he affects a certain jerkiness of style that in no small degree deteriorates his performance. It also wants the plaintive effect of the minor key. I confess I am not very learned in these matters, and a major cuckoo may not be so rare a bird on the earth after all; but I do not recollect ever having noticed one before. All the other cuckoos that I have remarked were *minors*, and, whatever may be the reason of the distinction, I cannot, at least, regard it as connected with difference of sex.

Some years ago I wrote to NATURE concerning a cuckoo who used to surprise me with a third note interposed between the mediant and the key-note. JOHN BIRMINGHAM

Millbrook, Tuam, May 21

Fall of Dust

EXTRACT from a letter to Sir B. C. Brodie, dated May 1:—

Campagne, Montfeld, Mustapha Supérieur, Alger

I WRITE to-day just to enclose you some curious red dust which fell all over Algiers last Saturday (April 24), the air quite still, and sky of a curious orange colour, everything looking as though seen through a yellow glass. The next morning this powder was swept up in large quantities in our court, all the flat roofs being also covered, and the flowers quite spoiled. It fell again the two following days, but rain followed and turned it

[1] "Auroræ and their Spectra," by J. Rand Capron, F.R.A.S. (London: E. and F. Spon, 46, Charing Cross, 1879.)

into mud, which stained our whitewashed walls a reddish brown. I see that it fell in Sicily on March 29 and 30. . . . It is quite a different colour from the dust the sirocco occasionally brings us.

Monkeys in the West Indies

YOU have recently had communications in NATURE (vol. xxi. p. 131 and 371) from two gentlemen residing in the Island of Dominica, in the West Indies, Messrs. Edmund Watt and John Imray, on the incorrectness of Prof. Mivart's statement, in his paper on "Tails," regarding the non-existence of monkeys in these islands.

These gentlemen are quite as much in error as Prof. Mivart in asserting that the only islands where monkeys are to be found are St. Christopher and Nevis, and Mr. Imray especially, who says, "It certainly appears remarkable that no species of monkey should exist in the wild state in any of these islands along the whole range from Grenada to Jamaica," with the exception of the two already named.

Not only are there monkeys in the Island of Grenada, but they exist in large numbers, and enjoy all the wildness that the deep forests of the mountains secure to them.

Riding across the country over the mountain ridges, these animals are frequently to be seen skipping amongst the branches of the surrounding trees, and they have often been shot by sportsmen who have ventured into the "high woods."

Exciting *rencontres* have been met with by those who have gone in pursuit of the monkeys. When one is shot at it sets up a "*houp, houp*," that, like the whistle of Roderick Dhu,—

> ". . . garrisons the glen,
> As if the yawning hill to heaven
> A subterraneous host had given,"

and from all sides you are pelted with nuts and seeds and boughs gathered from the trees by the offended tribe. Should you succeed in maiming or killing one of them, the survivors assume so threatening an attitude that, being as a rule singlehanded, you are quite content to retire from the scene of the contest, consoling yourself with the reflection that discretion is the better part of valour.

It is even difficult to secure the skin of one of these animals, for if there are numbers present, when one is shot the others bear away their injured brother beyond your reach.

It can therefore be readily understood how difficult it is to obtain one alive. Not long ago, however, I thought I had secured a prize. One of these "natives" was brought into the town for sale. He was such a handsome fellow, and looked so interesting, that I determined to purchase him. What I was particularly struck with was his being so tame, as he allowed me, without moving a muscle, to place my hand upon his head and about his face. Having been called away for an instant, I missed my opportunity, as he was taken by another gentleman who had come up in my absence. That same evening I saw him again, and on a closer examination I discovered the cause of his docility. He was blind! That was the reason he had been caught so easily.

It is not at all to be wondered at that neither Rochefort, Du Tertse, nor La Bat, the three earliest writers on these islands quoted by Mr. Imray, mention the existence of monkeys in Grenada. They had no opportunities of knowing it. La Bat alone travelled about the island a little, but this was only on our western coast, and the Caribs, who might have informed them on this subject and on many others, had been most carefully exterminated by their countrymen. D. G. G.

Grenada, April 27

IN a letter that appeared in NATURE, vol. xxi. p. 371, on "Monkeys in the West Indies," I observed that it seemed remarkable "that no species of monkey should exist in the wild state in any of the West India Islands along the whole range from Grenada to Jamaica," &c. Since writing the above I have discovered that monkeys are abundant in Grenada in the wild state, and that they are very destructive to the growing crops. Mr. Watt (now at Cape Coast Castle), who took exception to Prof. Mivart's statement in regard to the existence of monkeys in the West Indies, called my attention also to this fact.

Have these Grenada apes been introduced, or are they indigenous? is the question, if indeed it be a question. The historic evidence points, I think, conclusively to their introduction, though I have not been able to ascertain the when and the how, as in the case of St. Kitts. The two old French authors quoted in my former letter—Rochefort, 1665, and Du Tertse, 1667—enumerate the mammalia at that time existing in the Antilles as known to them, and Du Tertse was well acquainted with Grenada; but no species of ape is amongst the number.

A letter from Mr. Sclater in NATURE, vol. xx. p. 153, proved that the St. Kitts Monkeys were referable to the green monkey (*Cercopithecus callitrichus*, Geoffr.) of Western Africa. Can Mr. Sclater or any of your readers give similar information regarding the species of the Grenada ape?

I have been informed that apes are also to be found wild in Montserrat.

Sir Robert Schomburgk, in his "History of Barbados," says, with reference to the Quadrumana: "The most interesting [of the mammalia] is the Barbados monkey, now nearly extinct, although formerly so frequent that the Legislature set a price upon its head. I have much to regret, on account of natural history, that my endeavours to procure a specimen for the purpose of determining the species have entirely failed. From the outer appearance of a living specimen I consider it to be *Cepus* [*Cebus*?] *capucinus*, Geoffr., the Say, or Weeper, or a very closely-allied species. It is not likely that it was introduced, as the first settlers found it in large numbers on their arrival."

Prof. St. George Mivart, who stands in the foremost rank as an authority on all such matters, in an article on "The Geography of Living Creatures," in the *Contemporary Review* for February last, makes the following remarks:—"The West Indian Islands, again, are admirably suited for such creatures as apes, yet none are indigenous to that region, though they rapidly increase when they have been introduced." He says in a note: "Trinidad is really a detached part of the continent of South America."

As all the historic facts go to prove that no species of the Quadrumana existed in the Lesser Antilles when first settled, it certainly does appear much more probable that the apes stated to have been found in Barbados by the first settlers had been introduced from Trinidad or the South American continent than that they existed as native to the island. JOHN IMRAY

Dominica, April 24

The Recent Volcanic Eruption in Dominica

I AM indebted to Mr. Thomas Raine, of the Colonial Bank, Barbados, for the following analysis of the volcanic dust which fell in Roseau—the capital of that island—and the surrounding country during the eruption from the crater of the "Boiling Lake" on January 11 in the present year. The analysis was made in the Analytical Laboratory, Barbados, on January 19, by Mr. George Hughes, formerly senior assistant to Dr. A. Voelker, F.R.S., the sample of volcanic dust having been collected during the eruption and forwarded immediately afterwards to Barbados. Mr. Hughes thinks that the dust "has not been exposed directly to the action of fire to any extent, or the percentage of oxide of iron would have been higher and the pyrites less—oxide of iron being one of the products from the combustion of pyrites."

Aluminia	·64
Moisture	3·26
Oxide of iron	·45
Sulphate of iron	14·46
Sulphate of lime	1·42
Carbonate of lime	·39
Magnesia	·32

EDMUND WATT

Government House, Cape Coast, West Africa, April 23

Cup Stones, Cup-Marked Stones, or Cups and Rings

THE interesting paper on "A Scottish Crannog" in NATURE, vol. xxii. p. 13, is illustrated on p. 16 by an engraving (Fig. 3) which exactly represents the "Cups and Rings" that have long excited the curiosity of anthropologists on Rombald's Moor, near Ilkley, West Yorkshire. These markings, which I have examined within the past week, are on detached flattish rocks of millstone grit, immediately to the south-west of the village of Ilkley, and near to what are known as the Panorama Rocks.

On one piece of rock there are at least thirteen of the markings visible, and the rings or grooves round the central depression vary in numbers from one to six. Mr. Joseph Lund, of Overdale, Ilkley, who most politely guided me to the stones in question, also showed me, in his own garden, a large block of grit, bearing some of these markings, *from each of which is a district channel cut to the edge of the rock.* There have been many theories as to the significance of these markings. Has their use been yet ascertained?

R. MORTON MIDDLETON, Jun.

West Hartlepool, May 15

A Double Egg

THE other day on opening an egg, certainly a fine one, I found inside another perfect egg, so far as shell and the white part are concerned, but with only a faint streak of yellow for yolk. Double yolks are common, but I never saw, or read of, a perfectly formed shell inside an ordinary one before. If you think it worth notice, I send it for that purpose. T. ALLWOOD

Stafford, May 14

COMPARATIVE ANATOMY OF MAN[1]

II.

WITH regard to the cranial characters of the Americans the same difference of statement is met with as in respect to their external appearance. Morton's assertion of the general sameness in the skulls from all parts of the continent has been contested by others. But the controversies relating to this subject have nearly all turned upon one character alone, that is, the relative breadth of the cranium compared to its length, to the neglect of many others probably of equal importance. The prevalence of artificial cranial deformity, spoken of in a previous lecture, causes some difficulty by limiting the number of crania possessing their natural form at our disposal; but still there is sufficient evidence to show great variation in the cephalic index of American skulls. Although such extreme dolichocephaly as is met with among the Eskimo is very rare among true Americans, the larger number of crania of Indians, excepting those inhabiting the west coast of North America, and the region west of the Andes in South America (Peru and Bolivia), as well as Patagonia, in all of which regions brachycephaly prevails, are either mesaticephalic or moderately dolichocephalic. But the two forms are curiously intermixed, or at all events found in different tribes inhabiting contiguous regions, much, in fact, as they are in Europe. As the inhabitants of the two extreme ends of the continent, the Eskimo and the Fuegians, are both dolichocephalic (though in the case of the latter the evidence of cranial form is not yet so complete as might be wished), and as certain skulls, apparently of great antiquity, which have been discovered in Patagonia and Brazil are of the same form, it has been conjectured that the primitive inhabitants of the continent were a race with long and narrow heads, and that the brachycephalic race are later intruders.

The characters of the skeleton of the face exhibit, as is so often the case, greater uniformity than those of the cranium proper. The frontal region is almost universally low and retreating, and the supraciliary ridges generally well developed in the males. This and the form of the nose distinguish them from the majority of Asiatic Mongols. Nasal bones, compressed laterally, hollowed near their upper end, and forming a salient projection forwards at the lower end, giving the characteristic high bridge to the nose of the living face, are found in the great majority of American skulls from all parts of the continent. The tendency to a narrow form of nasal aperture (so very marked in the Eskimo) prevails throughout the American continent, the average index of 123 specimens being 47·2, which is almost as low as that of Europeans, while a really platyrhine nose, such as is the rule among negroes and Australians, is rarely, if ever, met with. The form of the orbit is also characteristic, being almost invariably large, round, and high, having an average index in 129 examples of 91·5. In the artificially-flattened heads this index is greatly increased, as the depression of the forehead drags the superior margin of the orbit upwards, often so much as to cause the vertical height to exceed the horizontal diameter. The malar bones are always full, and project laterally, and the nasi-malar angle, though somewhat diminished by the saliency of the nose, approaches to that characteristic of the Mongolian races. In the projection of the jaws forwards the skeleton of the face holds an intermediate position between the orthognathous white and the prognathous black races, in a great many cases inclining towards the latter. The lower jaw is large and the chin fairly prominent; the teeth are of moderate size and vertically implanted. Morton found the average cranial capacity of 155 ancient Peruvian skulls to be as low as 75 cubic inches, less than that of almost any other known race. It has been thought that some error may have crept into his method of measurement, but his estimate is probably not far wrong, as the average of 47 male skulls in the College collection is 1,345 cubic centimetres, or 82 inches, and of 50 females, 1,194 c.c., or 73 inches, giving a mean for both sexes of 77 cubic inches. On the other hand the barbarous tribes of Indians of both North and South America gave, in Morton's hands, an average capacity (for both sexes) of 84 cubic inches, and the Chinooks, from the mouth of the Columbia River, have remarkably capacious skulls, the average of 7 males in the College being 1,589 c.c. (97 inches), larger than those of any other race, but these may be rather exceptional specimens. It is, however, perfectly certain that the crania of the comparatively civilised Peruvians were much smaller than those of either the Indians of the North-West, or the Patagonians, or even Fuegians; but, as Morton remarks, the former, living under a thoroughly organised paternal despotism, seem neither to have thought nor acted except at the dictation of a master, while the brain of the savage was always in a state of activity to provide against the necessities and dangers of his daily life. But it must be recollected that the stature of the Peruvians was much less than that of the hunting tribes, and it is also possible that the difference may depend partly upon some general law connecting the size of the brain with the prevailing temperature, as inhabitants of cold regions have usually a larger brain capacity than those who dwell within the tropics.

The general characters of the American cranium are thus rather negative than positive, but on comparing it with the cranium of other races, it will be seen that it has no affinity whatever with that of any of the negroid people, Australians, Melanesians, or true negroes. From these it differs in every essential character, but with the Mongolian cranium it presents many affinities, especially in the form of the orbit, the narrowness of the nose, and the great size and forward projection of the malar bones. It is by the latter character especially that it differs from the European cranium. The prominence of the nasal bones is sometimes the only distinction to be found between American and North Asiatic skulls. Although Mongolian in the general type of face, it never presents such an extreme exaggeration of that type as is to be seen in the Eskimo, from which it can always be readily distinguished. The best argument for the unity of the American race (using the word in a broad sense) is the great difficulty of forming any natural divisions founded upon physical characters. Although certain special modifications prevail in different districts, and the Mongolian resemblance is greatest on the north-western coast, the same form constantly reappears at widely separated parts of the continent. Skulls from Vancouver's Island, from Peru,

[1] Abstract Report of Prof. Flower's lectures at the Royal College of Surgeons, March 1 to March 19, on the Comparative Anatomy of Man. Continued from p. 61.

and from Patagonia, can be shown which are almost undistinguishable from one another, but the materials at hand, at all events in European collections, are not yet sufficient for following out this interesting investigation to a satisfactory conclusion.

Races of Africa.—Of the great primary divisions of the human species no one is more distinctly characterised than the Negroid race, if under this term we include the whole of the dark-coloured, frizzly-haired people who inhabit considerable portions of the equatorial region of the so-called Old World, from the West Coast of Africa eastward to the middle of the Pacific. The oceanic branches of the group are not at present under consideration, but only those which inhabit the continent of Africa. The physical features of the Ethiopian negroes have remained unchanged since the earliest historic period, as they are depicted in ancient Egyptian drawings much as we see them now, but geographical and geological considerations tend to indicate a much vaster antiquity for the race. The present northern limit of the negro population of Africa, extending from the River Senegal on the west across the continent in a nearly due easterly direction, corresponds with the Ethiopian region of zoologists, characterised by a fauna altogether different from that of the more northern parts of the continent. The cause of this difference is accounted for by the undoubted fact that at a comparatively recent geological epoch the Sahara was covered with sea, and the portion of Africa lying to the south of it was isolated from the great continental track composed of Europe, North Africa, and Asia. The distribution of the races of man so closely coincides with that of the remainder of the fauna that it is natural to suppose that it [must arise from the same cause, and we may thus attribute to the long separation of the races north and south of the Sahara, during the period in which the waters of the Atlantic flowed over it, their strongly opposed physical characteristics. Since the two races have come in contact by the drying up of these waters much intermingling has taken place along the frontier line, but, considering the immense period of this stage of their existence, it is remarkable how little the original geographical boundary has been shifted.

The physical characters of the negro, in his most typical form, as found in the equatorial regions of Africa, have attracted much attention from anatomical anthropologists. In discussing the possible range of differences between different members of the human species the African negro has, on account of his structure being better known than that of any other of the lower races, always been taken as the antithesis of the white man of Europe, and in numerous treatises on the subject the differences between them have often been either exaggerated or softened down, according to the bias of the writer. The black colour of the skin of the negro, due to an increased number of pigment granules in the cells of the epidermis, is proverbial, but very few negroes, if any, are really black. The Joloffs of Senegambia are described as being "jet black," or even "blue black," but various shades of brown, or even yellow, are more common. The iris is dark brown and the conjunctiva yellowish. The hair is always black, except in the not unfrequent case of albinism. Its peculiar character, its flattened elliptical section, and tendency to assume very close spiral coils, giving the general effect commonly called "woolly," or more properly "frizzly," are well known. The division of the negro races into two distinct groups, those in which the hair grows evenly scattered over the scalp (*eriocomi*) and those in which it grows in distinct tufts, with bare intervals between (*lophocomi*), though often demonstrated to have been based upon fallacious observations, holds its ground with great tenacity, and is still adopted in most treatises on anthropology. The report of a committee of the Paris Anthropological Society on the growth of the hair of a negro in one of the hospitals of that city, published last year in the *Bulletin* of the Society, ought to set the question at rest for ever.

The features of the negro are so well known as scarcely to need description. Their chief characteristics are, a narrow but rather vertical forehead, small but rather prominent eyes, full cheek bones (intermediate between those of European and Mongolian), flat broad nose, prognathous mouth, with very full and everted lips, often projecting beyond the level of the nose, large white teeth, and a small chin. In stature there is considerable variation, some tribes being equal or even above the average of Europeans, others much smaller, and there is some evidence of the existence of a true race of pygmy negroes in the interior of Africa. Two thousand black soldiers of African descent in the United States of America, carefully measured during the war, gave an average of 66·21 inches, or nearly one inch below the average of whites (67·15). The difference in the proportions of the different parts of the body in different races have received much attention from anatomists, and comparison between the negro and the standard European is more completely elaborated than that between any other races; but owing to the paucity of skeletons, on which alone perfect accuracy of measurement can be obtained, much still remains to be done. As regards the length of the clavicle, Broca and Pasteau find that this bone is slightly longer in the negro than in the European, that is as compared with the humerus; but the comparison is not a satisfactory one, the latter bone being, as will be shown, peculiarly short. Compared with the femur, which is a better standard, as its proportionate size to the height is nearly the same in the two races, the clavicle (as far as the materials available permit the comparison) appears to be shorter than in the European, as was shown last year to be the case with the Andaman Islanders. The differences in the form of the scapula have been fully described by Broca and Livon of Paris. All observers agree that the arms of the negro are longer in proportion to the height than are those of Europeans. This is illustrated by the measurements taken in the American war, which show that when standing upright the mean distance between the tips of the fingers and the upper end of the patella was 2·88 inches in the negro, and as much as 5 inches in the white. The legs are also longer in proportion to the height, though to a less extent. The arms, compared to the legs, are slightly shorter than in Europeans. This is caused by the shortness of the humerus, its length as compared with the femur being as 69 to 100 in the negro and 73 to 100 in the European. The radius is longer even as compared with the femur or with the height, and *à fortiori* as compared with the humerus. The humero-radial index is therefore one of the most characteristic distinctions between the two races. In Europeans it averages 74 (the humerus being 100), in negroes 80. The femoro-tibial index presents a similar but less striking difference, being in Europeans 82, in negroes 85. Some of these characters, as the humero-radial index, approximate the proportions of the negro to those of lower forms, but others, as the shortness of the humerus and the greater length of the lower limbs as compared with the height, do not do so, and only present signs of divergence from the European standard, but not of inferiority. The other black races agree generally with the typical African negro in such proportions as he differs from the European, and hence these might be used as valuable distinctive characters in the classification of man; but difficulties arise when the negro is compared, not only with the European, but with other races generally held to be distinct. Although very few of them have been measured in sufficient numbers to give reliable averages, the indications already obtained show that in many points the proportions, though they may distinguish the negro from the European, do not separate him from others, which in many respects are most dissimilar. In the humero-radial index, for instance, the Peruvian and

the Malay (judging by the skeletons in the College Museum) agree with the negro rather than with some other branches of the so-called Mongoloid races, as the Eskimo and the Samoyede. But this is a subject for further observation rather than hasty generalisation.

The difference between the pelvis of the African negro and that of the European has been pointed out by Vrolik and others. It consists mainly in the increase of the antero-posterior diameter as compared with the transverse, expressed by the pelvic index, or ratio between these diameters, the latter being taken as 100. In the European male the average index is 80, in negroes, according to various observers, from 90 to 100. As in the proportions of the limbs, many of the Mongoloid races conform in the characters of the pelvis rather with the negro than with the European.

In the cranial characters the distinctions between the negro and the white races are strongly marked. The average capacity of the cerebral cavity is undoubtedly smaller in the former, even in individuals of approximately the same height. It is, however, considerably higher than in the Australian. The difference between the average capacity of English and negro crania in the College Museum is 123 cubic centimetres, between the latter and the Australian 80 c.c. Broca's totally independent measurements of skulls at Paris give a difference in the former case (Parisians being substituted for English) of 128 c.c., and in the latter of 83 c.c., so that the results are substantially identical. The general form of the cranium is expressed by the cephalic or latitudinal index, or relation of breadth to length, the latter taken as 100. The average index of forty-two negroes of various tribes in the College Museum is 73·6. Of these more than half are between 70 and 75, or dolichocephalic; less than half are above 75, or mesaticephalic; but very few are either below 70 or above 80. The average index of eighty-five negroes from the West Coast of Africa, measured by Broca, is 73·4, and of fifty-three from East Africa, measured by Lederle, is 73·9. These remarkable agreements with our own measurements show that between 73 and 74 may be fairly taken as a general average of the cephalic index of the African negro, and that he belongs, therefore, to the moderately dolichocephalic races. The height, measured from the basion to the bregma, is almost identical with the breadth, the average of the forty-two College specimens giving 73·5. The negro skull in these proportions differs greatly from that of the Fiji Islanders previously described. Differences in the position of the foramen magnum, in the angle formed by its plane, with the horizontal of the skull, and in the various facial angles, which have been pointed out as characterising the negro skull as compared with that of the European, can only be explained by means of diagrams. The facial characters are generally eminently characteristic. The forehead, though narrow, is not retreating. The glabella and supra-orbital ridges are sometimes well developed, but more usually this region is smooth and flat. The orbits have a moderate index, 85·5 (Broca), or 86·3 according to measurements of the College collection. The nose is distinctively platyrhine, the average index being 55 or 56. The nasal bones are small and flat, their external surfaces directed forwards, the two meeting in front at a very open angle, instead of a narrow one as in Europeans. The lower margin of the nasal aperture is usually rounded off instead of sharp and strongly defined. Equally characteristic is the prognathism, which is very rarely absent. The measurement from the basion to the middle of the alveolar border is greater than that from the basion to the nasofrontal suture, whereas in Europeans the reverse is almost always the case.

The teeth are regular, well developed, and generally free from caries. The third molars (wisdom teeth) appear to be always in their place before the closure of the basilar suture, whereas among Europeans they are often much later in coming into place. The size of the teeth varies in different races, but hitherto no accurate measurements have been made to express their difference. The length of the molar series, in a straight line between the anterior edge of the first premolar and the posterior edge of the third molar, may be conveniently used to indicate the size of the teeth, and called *d*. This may be compared with the length of the cranio-facial axis, or basi-nasal length (B N), and a dental index formed from $\frac{d \times 100}{\text{B N}}$. This will give at all events a fair approximation to the relative size of the teeth compared with the skull, as the length B N is one of the least liable to variation of any in the cranium. Unfortunately for the investigation, in a large proportion of the crania in Museums the teeth are wholly or partially lost, and a larger number of specimens must be measured than are at present available. The following indices (which must be regarded as provisional) are however of considerable interest. In the first place it must be observed that the teeth of women, though smaller absolutely, are larger relatively to the cranio-facial axis than those of men. For instance, in Europeans the dental index of males is 40·5, of females 42·0. In Australians the disproportion is greater still, being 45·7 for the males, and 48·4 for the females examined. In the following table males only will be included. Europeans 40·5, Ancient Egyptians 40·8, Hindoos 41·2, American Indians 42·5, Chinese 43·8, African Negroes 43·9, Andamanese 44·2, Fijians 45·4, Australians 45·7. It will thus be seen that in the size of the molar teeth the negroes hold an intermediate position between Europeans and Australians, but approaching nearer to the latter. The actual average length of the molar series in European males is 40·8 millimetres, in Africans 45·4, in Australians 46·7. The anthropoid apes give a higher index than that of any of the races of man.

(To be continued.)

ON SYSTEMATIC SUN-SPOT PERIODICITY

At the present moment, when a good deal of attention is being directed to sun-spots and their possible influences, it may not be amiss to discuss the question of their systematic periodicity.

We have to ask ourselves whether we can by a limited application of labour so disentangle the apparently complicated and capricious phenomena of sun-spots as to exhibit certain well-defined recurring periods, the superposition of which upon each other may ultimately explain the march of these phenomena. It will be apparent that such an analysis of the past is the first and indispensable step towards any prediction for the future. I will now bring before the readers of NATURE the first results of an attempt of this kind. As the subject will be more fully discussed in another place, I will in the meantime mainly exhibit the results obtained, referring as briefly as may be to the method used in procuring them. The method is that which (in conjunction with Mr. Dodgson) I have already brought before the notice of the Solar Physics Committee and of the Royal Society. It has been applied to thirty-six years of sun-spot observations, beginning with 1832 and ending with 1867. The first portion of these has been derived from the records of Hofrath Schwabe, the second from those of Carrington, while the latter portion has been derived from De la Rue's Kew series. My first object has been to ascertain to what extent these records exhibit indications of certain systematic inequalities having periods not far differing from twenty-four days. I will limit the present communication wholly to this issue.

These thirty-six years have been split up into three series of twelve years each, and treated after the manner

TABLE I.—Exhibiting a Sun-Spot Inequality of Period 24·022 Days for every Four Years from 1832 to 1867, and also for every Twelve Years

which is fully described in the communications already alluded to. By this means the positions of the various inequalities around twenty-four days have been indicated on the time-scale. I have next taken two of these and attempted to eliminate from them the influence of all neighbouring inequalities, in order to see with what success it is possible to disentangle the various periods from each other. In order to test this success I have exhibited in the tables on p. 81 the result of this elimination applied to each four years of sun-spot records, and I think it will be manifest to every one that there is such evidence of repetition, that one cannot doubt the reality of the periods therein indicated. I have likewise begun to apply to these records Gen. Strachey's test, and with a good result so far as I have yet gone.

No kind of smoothing or equalisation has been applied, and the elimination has been carried on only to the first stage, so that more accurate determinations will probably result from a further application of labour.

BALFOUR STEWART

PRIMITIVE MAN[1]

IT is a familiar fact that from time to time wrong-headed but enthusiastic persons appear in the scientific arena boldly challenging the truth of some one or other of the most firmly-established and essential doctrines of the scientific creed. Sometimes a clever investigator discovers that we moderns are all in the wrong, and that the sun after all goes round the earth; another will have it that the moon does not revolve on its axis; a third disputes the correctness of the theory of gravitation; whilst a fourth finds no difficulty whatever in squaring the circle. Such men have cropped up at intervals throughout the historical period. They are not without their usefulness in their generation, for they afford some little mirth, and give an opportunity sometimes to men of science to reconsider their standpoints and settle themselves more firmly upon them. It seems uncertain whether Prof. Dawson, of McGill College, Montreal, is to be classed with these malcontents, or whether his scientific heresies are to be explained as conforming to the general law that superstitions generally survive and even thrive in colonies long after they have died out in their mother country.

No greater contrast could well be conceived than is presented by the two works on Primitive Man which have just appeared, and which form the subject of the present article.

Prof. Boyd Dawkins, in accordance with the teachings set forth in his "Cave Hunting" and all other works which have proceeded from his pen, treats his subject in a thoroughly scientific and unprejudiced manner, and the results which he lays before his readers are in keeping with the conclusions now fully accepted by all anthropologists and admitted by educated persons generally. Prof. Dawson, on the other hand, has actually written a book at this present time, the object of which is to attempt to show that mankind first made its appearance on the earth not more than 6,000 or 8,000 years ago. He sums up thus:—"What evidence the future may bring forth I do not know, but that available at present points to the appearance of man with all his powers and properties in the Post-glacial age of geology, and not more than 6,000 to 8,000 years ago." His book is described as "an attempt to illustrate the characters and condition of prehistoric men in Europe by those of the American races." His arguments are old stagers long ago upset. Such, for example, as that because some savages, such as the Veddahs of Ceylon, who are degraded Singhalese, are degenerate, therefore all savages are the degenerate offspring of highly-cultivated races. On similar grounds we might infer that because barnacles and ascidians can be shown to be degenerate animals, therefore all lower animals have undergone "degeneration," to use Prof. Ray Lankester's term, and all monkeys are degenerate men.

The main argument of the book is however apparently that derived from the results of excavations made on the site of Montreal. On this site, as we know from Cartier's narrative, stood in 1535 the native town of Hochelaga, which was fortified, as shown in the plan of the town at the end of the third volume of Ramusio's collection of Voyages and Travels, by means of a circular triple wall of wooden beams, the outer of which were inclined to meet one another at the summit. The native town, its huts and walls, naturally disappeared within a century, and all that now remains of it are the implements and bones which are to be dug out on its site, and of which Prof. Dawson gives an interesting account. There are tobacco pipes of various kinds, stone weapons, pottery, and bones of animals and men. If it had not been for Cartier's visit and published narrative antiquarians might have ascribed a very early date to these remains, argues the author, therefore in all cases where a very early date has been assigned to human remains of the palæolithic age in Europe a similar error has been committed. We cannot follow Prof. Dawson through his attempts to contort the data of modern science into accordance with Chaldæan cosmogonies and mythology as familiar to us in Jewish dress. He gravely refers the remains found at the camping ground at Solutre which, according to M. de Mortillet, mark a special epoch (the Solutrian) in the palæolithic age, to the *antediluvian* epoch, and reminds us how Jabal, before the flood, according to Genesis, initiated the nomadic mode of life, suggesting that the old inhabitants of Solutre who hunted the mammoth, the cave lion and cave bear, were Jabalites. It is delightful to find how beautifully everything fits into its place when freely interpreted by Prof. Dawson. The results of his ethnographical and antiquarian researches appear to be more or less summed up in the biblical text, "God shall enlarge Japhet, and he shall dwell in the tents of Shem, and Canaan shall be his servant." This means, as he aptly explains, that the Aryan or Japetic races were to be endowed with "the higher control of the physical forces and the greater power of expansion and propagandism," in short, amongst other exploits, to exterminate the Redskins and colonise America; whilst the Semitic races were to receive historical and spiritual revelations, and Canaan in the text represents unprogressive humanity generally.

Prof. Dawson's intimate acquaintance with the details of prehistoric religion is most startling. He holds up the faith of palæolithic, or *palæocosmic*, man, as he prefers to call him, as a warning and a pattern to the degraded Ritualist, at whom he cannot help having a dig even with palæolithic weapons, being evidently a staunch Protestant. He slays evolutionists with the same thrust. It is an unexpected honour for them to die in such company. No doubt the association is meant to give the Ritualists the hardest dig. He wishes "distinctly to affirm that the prehistoric religions, and what we call heathenism or animism of untaught tribes, were nearer to God and truth than are either the ritualisms and idolatries or the materialistic scepticisms of more civilised times, when men, 'professing themselves to be wise, become fools.'" Till we read this passage it seemed to us that Prof. Dawson professed himself throughout his book to be very wise indeed, but of course he cannot have intended to pose in that attitude. The chapter concludes by calling on "all men everywhere to repent," and so we do heartily of having followed so far Prof. Dawson's, shall we call it "wisdom"?

We turn with relief to Prof. Boyd Dawkins's fine volume. It is sumptuously printed, and contains 168

[1] "Early Man in Britain and His Place in the Tertiary Period." By W. Boyd Dawkins, M.A., F.R.S., &c. (London: Macmillan and Co., 1880.) "Fossil Men and their Modern Representatives." By J. W. Dawson, LL.D., F.R.S., &c., McGill College, Montreal. (London: Hodder and Stoughton, 1880.)

excellent illustrations, the sources of which are given in a table at the commencement of the work, a detail of importance often omitted.

The first chapter deals with the relation of geology to archæology and history, these three sciences all contributing to the building up of the account of early man in Britain. There appears to be a slip in the table showing the specialisation of mammalia in the tertiary period,

FIG. 1.—Flint River Drift Implement, Gray's Inn Lane, ¼.

where the period is divided into the eocene, miocene, pleiocene, pleistocene, prehistoric, and historic stages. The latter stage is said to be characterised by living species of mammalia and no extinct species, which is rather misleading, since Steller's sea-cow is almost certainly extinct, and several other mammalia are verging on extinction.

After an interesting sketch of the physical conditions and the successive faunas and floras of preceding geological periods in Britain, the account of the miocene age is concluded with a paragraph headed "No Proof of Man in Europe in the Miocene Age." High authorities such as Dr. Hamy and M. de Mortillet have maintained that man did exist in France as early as the middle of the miocene age, basing their conclusions on the evidence given by splinters of flint found in mid-miocene strata at Thenay by the Abbé Bourgeois, and by a notched fragment of a rib found at Pouance by M. Delauny. The author seems a little in doubt whether these flakes and notches are in reality artificial, but if they be so he prefers to conclude, with Prof. Gaudry, that they were made by the anthropomorphous apes then inhabiting France rather than by man. This appears to be a somewhat wild suggestion, and the author is evidently led to it by considerations which are set forth in the same paragraph, and which seem to him to prove that from zoological grounds man could not have existed in the miocene age, as to the cogency of which considerations we cannot at all agree with him. His argument is that because no other living species of land mammal has been met with in the miocene fauna, therefore man could not have formed an exception to this supposed rule, and "had no place in a fauna which is conspicuous by the absence of all the mammalia now associated with him." "If miocene man had existed it is incredible that he alone of all the mammalia living in these times in Europe should not have perished or have changed into some other form in the lapse of ages." The author adds: "Those who believe in the doctrine of evolution will see the full force of this argument against the presence of man in the miocene fauna not merely of Europe but of the whole world." Now we, we hope in common with all the readers of NATURE, are thorough-paced evolutionists, but we should have said rather that those who understand the doctrine of evolution would consider this argument as completely unsound. Evolution, wherever variedly manifested in its action, does not produce any comprehensive similar effect on any group of different objects on which it acts. According to the varying conditions partly surrounding, partly embodied in each object, evolution singles out certain of the objects for higher specialisation, others for degradation, others again for extinction; whilst others again it, as it were, leaves alone to survive unchanged through ages amongst hosts of modified descendants of their near relatives. The survival of some form, larval or adult, or of some organ of great antiquity in unchanged condition, where all the concomitants have become profoundly modified, is one of the most familiar facts explained by the evolution theory. How is it else that the brachiopod Lingula has survived in nearly identical form to the present day from the earliest geological times, whilst all its then contemporaries are extinct or have changed? How is it else that the vertebrate structure survives in

only one or two of the degenerate Ascidians? How is it else that some savages are still in their stone age, and that Prof. Dawson still believes that mankind is only 6,000 years old?

We see no reason whatever, from evolutionary grounds, why man should not have existed in the miocene times. Anthropomorphic apes were already in those times abundant and varied, and comparative anatomy points to the progenitor of man having been an ancestor of the present existing anthropomorphs, combining many of their several characters. At the same time we do not wish to appear to assert that man did then exist, but we think it rather a pity that the author did not give good illustrations of the miocene flint flakes and the notched rib if only to show, as we believe is the case, that they do not exhibit any very definite traces of handiwork, and has not formed a more certain judgment as to whether the objects are artificial or not.

We have dwelt upon this matter at some length, because an important question of principle is involved in which we are at variance with the author. With regard to everything else in the book we cannot but offer our best thanks to him. His extended experience in cave-hunting, his critical knowledge of geology and of the later tertiary mammalia, have long rendered him an authority of first rank on the subject of which he treats, and he has in the present volume combined with great care all available published information with the results of his own investigations. The book represents with great clearness the present state of our knowledge with regard to the antiquity of

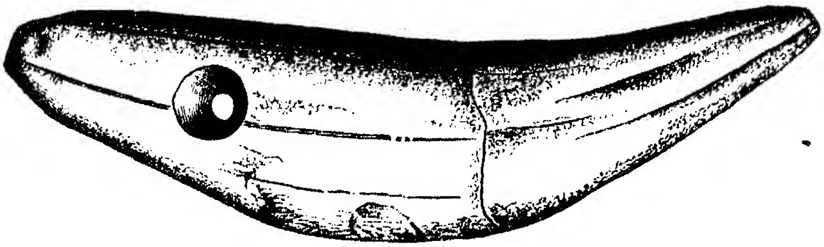

FIG. 2.—Tooth of Cave lion, Duruthy Cave. ½.

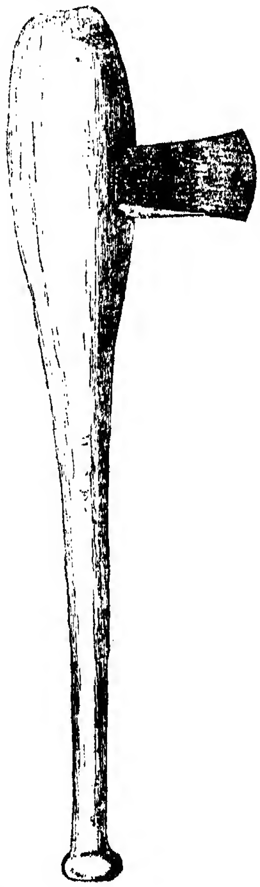

FIG. 4.—Stone hatchet, Robenhausen,

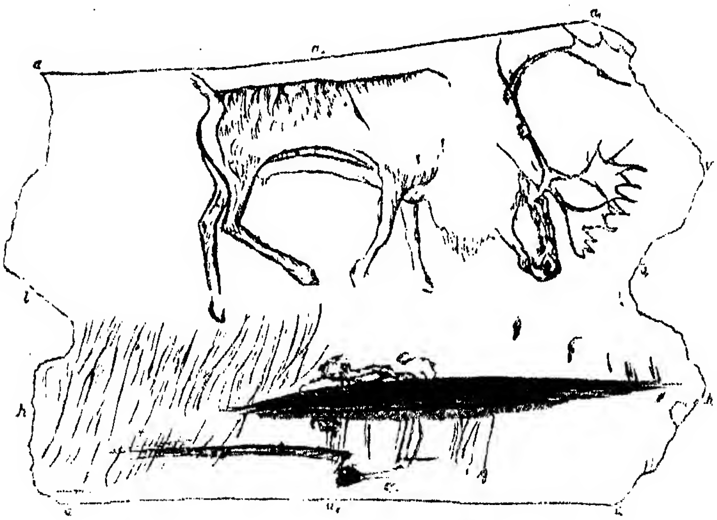

FIG. 3.—Reindeer incised on antler, Kesserloch, ⅔.

man, for though it treats principally of Early Man in Britain, no details of importance with regard to discoveries bearing on the subject on the Continent or elsewhere are omitted.

The whole account is most clearly and logically arranged, and written in a very readable and entertaining style. It is popular as well as scientific.

The author considers the evidence of man in early pleistocene strata as doubtful. It is in the mid-pleistocene deposits that man first appears without any doubt, as proved by flint implements found in the lower brick-earths at Crayford by the author himself. Man was at that period associated in the Thames valley with six extinct species of mammalia, viz., three species of rhinoceros, *R. megarhinus*, *tichorhinus*, and *leptorhinus*, the mammoth and *Elephas antiquus*, and the Irish elk. Large herds of horses, stags, and bisons frequented the open country, the hippopotamus floated about lazily in the Thames, whilst the thickets were inhabited by wolves, foxes, brown and grisly bears, huge lions, hyænas, and wild boars.

We cannot here follow the author throughout his well-told story, but can only dip here and there into his work to give our readers a sample of its qualities. Most interesting is a palæolithic implement discovered in England so long ago as the year 1690. It was found with the remains of an elephant in the heart of London in the gravel at Gray's Inn Lane, and having been preserved in the Sloane collection in the British Museum for more than 150 years, was ultimately recognised by Mr. A. W. Franks as identical with those discovered so long afterwards in the gravels of Amiens and Abbeville. It belongs to the late pleistocene river deposits. The accompanying

figure of it is taken from Mr. John Evans's "Ancient Stone Implements."

The author carefully considers, as far as the evidence will permit, the question of the range of the Cave men as compared with the River-drift men. The remains of the "Cave men," who are characterised by the use of certain peculiar implements, are found throughout the whole of France, and are remarkably abundant in the caverns of the Pyrenees. They occur also in Switzerland, Germany, Belgium, and England, but are limited in range, being unknown as yet in the caves south of the Alps and Pyrenees, and north of a line passing east and west from Derbyshire through Belgium. The Cave men differed in race from the River-drift men. They were ignorant of pottery, but they had a varied assortment of implements and weapons of bone, ivory, and stone. They prized ornaments, and in the cave at Duruthy forty canine teeth of the bear and the lion were found perforated to form a necklace, "a magnificent trophy of the chase."

The Cave men were also artists, and engraved drawings of very considerable artistic merit on bones, ivory, and antlers. Their drawings of the mammoth on its own ivory are familiarly known. We reproduce here a figure of a reindeer incised on an antler from the Kesserloch, near Thaynigen.

Drawings of the great Irish elk, bisons, the ibex, and bears have also been discovered, but those of man are extremely rare, and comparatively badly executed. Mr. John Evans is inclined to hold that the River-drift and Cave men belonged to the same age and the same race, but the author concludes that they must be referred either to two distinct races or to two sections of the same race which found their way into Europe at widely different times; the River-drift men being of far higher antiquity in Europe, and probably having lived for countless generations before the arrival of the Cave men and the appearance of higher culture. "The discoveries of the last twenty years have tended to confirm the identification of the Cave men with the Eskimos."

The account of the Cave men is followed by that of the prehistoric period, of the neolithic civilisation, the age of polished stone implements and of the prehistoric farmer and herdsman. Wild boars, the great wild ox, the urus, the Irish elk, the reindeer, the brown and grizzly bear still inhabited Britain during that period. The Irish elk is remarkable for being the sole survivor amongst land mammalia from the pleistocene to the prehistoric age which has since become extinct. Its rarity in Britain forms a marked contrast with its abundance in Ireland. It has been found in England, near Newbury in Berkshire, and at Maybole in Ayrshire. In the neolithic period the dog, horse, sheep, goat, shorthorn, and hog were already domesticated.

"Of all the neolithic implements the axe was by far the most important. It was by the axe that man achieved his greatest victory over nature, by clearing the land of forest. It was immeasurably superior to the rude flint *häche* of the palæolithic hunter, which could not make a straight cut in wood, and which was very generally intended for use in the hand, without a handle. It is therefore chosen as the symbol of the neolithic culture."

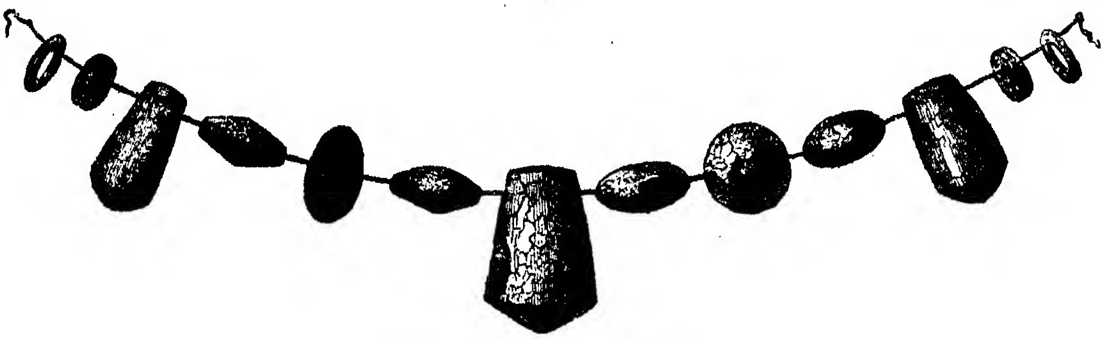

FIG. 5.—Amber necklace. Lake, Wilts, ⅔.

In New Guinea and its neighbourhood land is still cleared of forest by the natives for culture by the aid of fire and the stone hatchet.

Chapter X. treats of the further development of culture, the Bronze age, and the invasion of the British Isles by the Celts, who are proved by their tombs, scattered over the face of the country, alike in England, Scotland, Wales, and Ireland, to have conquered nearly every part of the British Isles. In the Bronze age the number and variety of the weapons, implements, and ornaments belonging to the men of the period become greatly increased, and their culture presents a far more complicated problem for study than that of their simpler predecessors. Mr. John Evans, who, as the highest authority on early bronzes, is followed by the author, divides the Bronze age into two periods—the Early and the Late; the first of these was a period of transition, when the use of bronze was superseding that of stone, and is characterised by the presence of bronze daggers and plain wedge-shaped axes, originally modelled from stone prototypes. The later division of the Bronze age is characterised by the appearance of swords, spears, palstaves, and socketed celts. Already in the early Bronze age such articles of advanced development as tweezers and combs of bone, amber and glass beads, jet buttons, and bronze finger-rings and ear-rings were in use. The accompanying woodcut represents an amber necklace of the Bronze period found at Lake, in Wiltshire. Even gold is found amongst the remains of this age.

We cannot follow the author in his account of the temples of the Bronze age, Avebury and Stonehenge, nor

FIG. 6.—Golden cap. Devil's Bit, Tipperary.

in his description of the methods by which the bronze was worked, of the artistic designs of the period, and of the curious hoards of bronze merchandise which have been found in France, and the pick of which has, we believe, found its way into Mr. John Evans' hoard. The twelfth chapter deals with the prehistoric iron age north of the Alps, the arms and equipage, personal ornaments, late Celtic art, Etruscan influence on art, &c. Arts in

this period reached a very advanced development indeed, as may be seen from the appended figure of a golden cap found in Tipperary. It is most beautifully ornamented in *repoussé*.

Silver and gold ornaments in this age became abundant. The concluding chapters in the book are on the Overlap of History (the Egyptian, Assyrian, Phœnician, and Greek Influences) and on Britain in the Historic Period (the Exploration of the British Coasts, and Roman Britain). We cannot follow the author further, but commend his book to our readers as one that will well repay perusal throughout.

THE HYDROGRAPHIC DEPARTMENT

WE observe that some of our contemporaries have opened their columns to certain strictures upon a public department standing well, and to our knowledge deservedly so, in the estimation of scientific circles in this and other countries.

It would appear that a Lieutenant of the Royal Navy, unknown, as we are informed, in his profession from the fact of his having retired from its active service at an early age, amused himself some few years back by a yachting excursion on the shores of Norway, in a small and crazy decked boat, undergoing, as might have been anticipated, some hardships in this excursion, which extended into the rigorous winter of that region. Gaining thus some knowledge of the coast traversed—but necessarily, from its great extent and intricate character, knowledge of a very superficial kind—the Lieutenant's experiences have recently formed the subject of an evening's entertainment at the Royal Geographical Society. Somewhat unfortunately for the ends of science and navigation, this adventurous cruise in a crazy barque has been in consequence dignified into a hydrographical survey, an appellation ludicrously inapplicable from the conditions under which the cruise was made, as related by the adventurer himself.

The ambitious *voyageur*, now extending his operations, under the leadership of an official of the Royal Geographical Society, has just addressed an audience at the Society of Arts on the "Trade Routes between England, Norway, and Siberia." We had expected at least some shreds of information on this topic, but find ourselves treated instead to a rude and ungenerous attack on the Hydrographic Department of the Admiralty, for some supposed shortcomings in its dealings with the officer, to whom the department had confided—mistakenly it seems—the revision of the sailing directions of that part of Norway on which the Lieutenant claimed to be an authority.

The Society of Arts commends itself to all reasonable men for the breadth and strength of its operations; we regret that it should in this instance have been exploited and made the arena, under cover of a legitimate object, for an attack, from personal motives, on a public department which has done and is doing good and honest service for the seamen of all nations. We believe we are only performing an act of merited justice in directing attention to the endeavours of a small, obscure, but self-asserting clique, bent apparently on discrediting a valuable and efficient department, affiliated in many ways to science, and well known to many of its ablest workers.

NOTES

PROF. W. H. MILLER died at Cambridge on Thursday, May 20, in his eightieth year. He graduated in 1826, being Fifth Wrangler, and shortly afterwards became a Fellow of St. John's College. He served his college as tutor during several years. On the resignation of Dr. Whewell in 1832 he became Professor of Mineralogy. He published his celebrated "Treatise on Crystallography" in 1838. This work was at once adopted by some of the most eminent foreign crystallographers, and may now be said to be universally accepted. It was translated into German and French. His "Manual of Mineralogy" appeared in 1854, and, like the former book, forms an era in the history of the science. It is full of the results of his own careful research. He is the author of several other books, and of numerous memoirs published in the various scientific journals. The memoir on the standards of weights is a classical research on the subject of weights, and is a monument of delicate and careful research. He was Foreign Secretary of the Royal Society, and was presented with the Society's gold medal in 1870 for his numerous contributions to science. Cambridge has especial cause to be grateful to him for the very splendid collection he has brought together. The collection consists almost entirely of donations; and the two noble gifts of the Hume and Brooke collections mark in a striking manner the appreciation in which Prof. Miller was held by lovers of minerals.

ON the same day as Prof. Miller died Prof. David Thomas Ansted, F.R.S., at the age of sixty-six years. Prof. Ansted was born in London in the year 1814. He graduated at Jesus College, Cambridge, was a Wrangler in 1836, and was elected in due course a Fellow of his college. In 1840 he was appointed to the Professorship of Geology in King's College, London. Five years later he became lecturer on geology at Addiscombe College, and also at the Civil Engineering College at Putney. About the same time he was made assistant secretary to the Geological Society, whose quarterly journal he edited for many years. From about 1850 down to a very recent date he was extensively engaged in the application of geology to the engineer's work, in mining, and in various other departments of industry. He has also been frequently employed as an examiner in physical geography under the officers of the Government Department of Science and Art. Prof. Ansted's works are very numerous; among them may be mentioned—besides his contributions to the transactions of learned and scientific societies—his "Application of Geology to the Arts and Manufactures," his "Physical Geography," his "Elementary Course of Geology and Mineralogy," and "The World we live in." Prof. Ansted was elected a Fellow of the Royal Society in 1844.

GENERAL MYER has sent a letter to his numerous correspondents, requesting, on behalf of the United States, that the hour for taking the simultaneous meteorological observations, from which are constructed the U.S. Weather Maps, be changed to a time thirty-five minutes earlier than at present; in other words, as regards the British islands, that the observations be made at 0h. 8m. p.m., instead of 0h. 43m. p.m. Greenwich mean time, and that the change be made to take effect on September 1, 1880. The proposed change being rendered necessary by the exigencies of the Signal Office, the request will doubtless be gladly acceded to.

THE second example of *Archæopteryx* is, we are informed, at present merely *on deposit* in the Geological Museum of Berlin, under the care of Dr. Beyrich, although it is expected that arrangements will shortly be made for its purchase by the authorities of that institution. It was bought from Dr. Haeberlein, of Pappenheim, by Herr Siemens, of Berlin, for the sum of 20,000 marks (1,000*l.*), in order to save it from an impending transfer to America, and to secure this valuable specimen for German science.

THE "Leopoldinische-Carolinische" Academy of Naturalists at Halle has presented this year's Cothenius medal to Dr. A. Michaelis, Professor of Chemistry at the Polytechnic High School of Karlsruhe, in recognition of his valuable researches in organic substances containing phosphorus.

AMONG the names mentioned for the honour of D.C.L. at the approaching Oxford Encænia is that of Prof. Sylvester.

WE regret to announce the death of Dr. Richard Biedermann, editor of the *Centralblatt für Agricultur-Chemie*. He died at Leipzig on May 10, at the early age of thirty-seven years.

IT is a fact worth noting that M. Chevreul, who is now in his ninety-fifth year, has begun his course on Chemistry at the Paris Museum of Natural History, with as much apparent zest and energy as he did fifty years ago when he first entered on his duties of that chair. The programme of his course, *Les Mondes* informs us, is beautifully and firmly written in his own hand. Notwithstanding his approach to the centenary, he still looks young and fresh.

A CORRESPONDENT, writing from Cherry Hill, Arnold, near Nottingham, informs us that he brought home from the Geisberg, in the autumn of 1877, a few specimens of the Edelweis, which he planted amongst some rock-plants in his pleasure-grounds situated on an eminence. It disappeared gradually altogether until last spring, when it came out to perfection. Towards the autumn he lost sight of it again, but a fortnight since signs of its reappearance were so developed that no doubt exists of its full growth, and in greater perfection than ever.

THE two first parts of a new botanical work by Dr. Dodel-Port, of Zürich, have just been published by Herr Cæsar Schmidt of that city. The title of the work is "Illustrirtes Pflanzenleben," and it promises to become one of unusual interest. In part 1 the lower fungi are described in a popular manner. The author undertakes to popularise the results hitherto attained in our knowledge of putrefaction- and contagion-fungi. He describes their forms, their size, and their manner of propagation; introduces the reader to their mode of life, and points out the danger arising to the human race from these minute organisms. The description is accompanied by two excellent plates, in one of which we recognise a reproduction on a small scale of a plate from the same author's famous "Atlas der Botanik für Hoch und Mittelschulen." Another chapter treats of miasma and contagions, and gives a complete account of the present state of our knowledge of infection-fungi. Part 2 is devoted to carnivorous plants, and is even more generally interesting perhaps than the first. The work is profusely illustrated with the author's original drawings. Altogether it is sure to form a very welcome and valuable addition to botanical literature.

THE death is announced of Dr. J. G. Mulder, Professor of Chemistry at Utrecht University. Dr. Mulder's name was well known in the scientific world; he died at the age of seventy-seven years.

THE Iron and Steel Institute holds its autumn meeting this year at Düsseldorf, by invitation of the German iron trade, on August 25 and four following days. An extremely interesting programme of excursions and meetings has been arranged.

AN interesting Report on the Meteorology of the Italian Mountains has been presented by the Rev. Prof. F. Denza to the International Congress of Alpine Clubs at Geneva. It appears that observations are regularly made at 113 mountain stations, the names, elevation, and geographical position of which are given in the report. Some of these stations, from their altitude and position, are of the greatest importance for the study of meteorology in the higher regions of the atmosphere. Three of them are specially worthy of notice, viz., Stelvio (2,543 metres), Valdobbia (2,548 metres), and Piccolo S. Bernardo. All stations are provided with good instruments, and meteorological observations are taken at some stations every three hours from 6 a.m. until 9 p.m. The results of the observations are carefully printed and circulated by Prof. Denza.

A GENERAL MEETING of the Mineralogical Society of Great Britain and Ireland will be held at the Meteorological Office, 116, Victoria Street, London, S.W., on Tuesday evening, June 1. The chair will be taken by Prof. T. G. Bonney, F.R.S., vice-president, at 8 p.m. The following papers will be read:—"On a New Face on Crystals of Stilbite, from Scotland and Western Australia," by the president; "On a Portable Chemical Cabinet for Quantitative Work," by A. E. Arnold (communicated by J. H. Collins); "On Kaolinite and Kaolin," by J. H. Collins. Other communications intended to be read at this meeting should be sent to J. H. Collins, Hon. Sec., care of Mr. R. H. Scott, at the above address.

THE Society of Telegraph Engineers have done valuable service to science by publishing the "Catalogue of Books and Papers relating to Electricity, Magnetism, the Electric Telegraph, &c., including the Ronalds Library," compiled by the late Sir Francis Ronalds, F.R.S. Some idea of the extent and value of this catalogue may be obtained from the fact that it occupies 560 pages. The work of editing has been carefully and judiciously done by Mr. A. J. Frost, who has prepared a useful memoir of Sir Francis Ronalds. The Catalogue contains 13,000 entries, though we regret that, by the conditions of the trust, the Society were not permitted to bring it up to date. They will, however, we are glad to learn, at no distant date, publish a supplement to the Catalogue, which will remedy this defect. The two together will form an invaluable reference-book in the subjects included in it.

IN reference to a note in NATURE, vol. xxi. p. 525, taken from the *Journal of Applied Science*, on the composition of the well-known Vevey cigars, Messrs. Grant, Chambers and Co., of Fenchurch Street, send us a letter from Ormond and Co., of Geneva, the manufacturers, in which they state that if such cigars exist as we referred to, "it can only be with the object of fraudulently taking advantage of the name of the goods we make, which have enjoyed an increasing reputation for more than thirty years past. The Vevey cigars manufactured by us are composed entirely of selected North and South American tobaccos, without any mixture or adulteration whatever."

A NEW scientific paper now appears at Leipzig every three weeks. It is called *Centralzeitung für Optik und Mechanik*. Dr. O. Schneider is the editor. The avowed object of the paper is to report on the progress in the manufacture of scientific instruments and apparatus, and in the scientific domain where such instruments and apparatus are employed.

A PROPOSAL has been set on foot for lighting the Sheldonian Theatre, Oxford, and the Camera of the Radcliffe Library with the electric light. In a circular addressed to the curators of the Theatre and of the Bodleian Library and to the visitors of the Ashmolean Museum by those interested in the question, it is stated that it has long been regretted by many members of the University that the Sheldonian Theatre is not available in the evening for any purposes of public interest, however great, for want of lighting. The neighbourhood of the Bodleian Library has, however, been a bar to any proposal for lighting by means of gas or any ordinary method. The care with which the heating apparatus of the Theatre has been inclosed within a fire-proof chamber is sufficient evidence of the importance attached by the curators of the Theatre to absolute security in this respect. The development of the electric light has now rendered it possible to illuminate public rooms by a process absolutely free from danger of fire. It has been adopted largely in the reading-rooms of our public libraries, and notably in the reading-room of the British Museum. The security is absolute and unquestionable, provided that the motive power is external to the building: the boon to readers in such reading-rooms is enormous. After dis-

cussing the question of the motive power and deciding in favour of a gas-engine, the memorial goes on to state :—"It is suggested that Dr. Siemens, F.R.S., D.C.L., to whom the electric light owes much of its recent development, might with advantage be consulted in connection with this proposal. Whether a permanent institution or an experimental trial is in question, all parties concerned can have the most perfect confidence that everything will be done as it should be in his hands. It is suggested that an experimental trial should be first made, which could be done at comparatively little expense. The memorialists feel confident that if this is conceded the permanent adoption of the light will follow." The memorial is already signed by Professors Henry S. Smith, W. Acland, H. Nettleship, Sayce, Sir Gore Ouseley, and Mr. Warren De la Rue.

THE enterprising Naturalists Society of Dundee had a very successful dredging excursion off the mouth of the Tay and in St. Andrew's Bay on Wednesday last week. Considerable hauls were obtained of familiar denizens of the coast waters, though we regret to learn that under the influence of the gentle swell in St. Andrew's Bay several of the budding naturalists suffered some disturbance of their equanimity, and we fear were not able to do perfect justice to the dinner and tea which were liberally provided on board. At the annual meeting of this Society a satisfactory report was presented, though we do not altogether approve of the movement for the publication of abstracts of the proceedings of the Society in the form of a journal. Such publications, we are inclined to believe, are more gratifying to the vanity of provincial societies than conducive to the promotion of science in any way. We see the Society is uniting with several other Scotch societies to endeavour to obtain the benefit of the Gilchrist Lecture Trust; why do they not take a hint from the line of action in reference to a journal, and endeavour to bring about a union of the various Scottish natural history societies for this and other purposes?

A CORRESPONDENT of the *Scotsman* writes that a colony of rooks has taken possession of a garden which is next to St. Magnus Cathedral, Kirkwall, and built about a score of nests. It is only two or three seasons since rooks made their first appearance in Orkney, and it is supposed the absence of trees in the country districts has caused them to take up their abode in the centre of the town.

Cotton is the title of a new weekly journal for manufacturers and planters.

AN important discovery is stated to have been made in the neighbourhood of Sydney, New South Wales. Boring for coal has been going on in Moore Park for ten months, and about the middle of March a quantity of oily matter was observed to come up, one gush lasting half an hour. This liquid is believed to be crude kerosene, but the analysis was not complete when the last mail left.

THE *Reale Istituto Lombardo di Scienze e Lettere* at Milan offers the following prizes:—For a treatise on Miasma and Contagions (Term May 31, 1881), a prize of 1,500 lire and a gold medal worth 500 lire. For determining by experiments whether the virulent principle of hydrophobia is an organised germ or not, a prize of 6,000 lire (Term February 28, 1882). For a descriptive treatise on the Motor-centres of the Periphery of the Brain, the sum of 2,000 lire (Term April 1, 1881). For the illustration by new research of the ætiology of cretinism and idiotism, 2,000 lire (Term May 31, 1882). Further details can be obtained by application to the Secretary of the Institution.

THE *Forester* is the title of a magazine published in connection with Nottingham High School, No. 7 of which has been sent us. The contents are varied, one paper being on the "Origin of Sandstones."

M. DEHAIRAN has opened the course of lectures that he is to deliver at the Museum d'Histoire Naturelle, on Vegetable Physiology. This chair has been recently created by M. Jules Ferry.

A SCIENTIFIC examination of the Ibaraki mountain range in Japan has resulted in the discovery of marble of different colours. One mountain is believed to be a mass of white statuary marble, and in another place black marble of the finest description was found.

THE additions to the Zoological Society's Gardens during the past week include a Black-faced Kangaroo (*Macropus melanops*) from South Australia, four Short-tailed Wallabys (*Halmaturus brachyurus*), three Vulpine Phalangers (*Phalangista vulpina*), three white-backed Piping Crows (*Gymnorhina leuconota*) from West Australia, presented by Sir Harry St. George Ord, C.B., F.Z.S.; a Javan Chevrotain (*Tragulus javanicus*) from Java, presented by Mrs. L. Dudfield; a Brown Capuchin (*Cebus fatuellus*) from Guiana, an Ocelot (*Felis pardalis*) from South America, a Ring-tailed Lemur (*Lemur catta*) from Madagascar, presented by Mr. Chas. A. Craven; a Pinche Monkey (*Midas œdipus*) from New Granada, presented by Mrs Henry Druman Macaulay; a Long-eared Owl (*Asio otus*), British, presented by Mr. G. E. Dobson, C.M.Z.S.; an Eyed Lizard (*Lacerta ocellata*), an Æsculapian Snake (*Coluber æsculapii*), six Viperine Snakes (*Tropidonotus viperinus*) from San Remo, North Italy, presented by Lieut L. L. Fenton; two Toco Toucans (*Ramphastos toco*) from Guiana, a Brown Passerine Owl (*Glaucidium phalænoides*), a Rusty Urubitinga (*Urubitinga meridionalis*), a Downy Owl (*Pulsatrix torquata*) from South America, deposited; two Guilding's Amazons (*Chrysotis guildingi*) from St. Vincent, West Indies, two Black-tailed Hawfinches (*Coccothraustes melanurus*) from Japan, four Golden Sparrows (*Auripasser euchlorus*) from Abyssinia, four Blood-breasted Pigeons (*Phlogœnas cruentata*) from the Philippine Isles, two Nightingales (*Daulias luscinia*), a Canary Finch (*Serinus canarius*), a Gannet (*Sula bassana*), British, purchased; a Black Wallaby (*Halmaturus ualabatus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE LATE PROF. PETERS.—Prof. Christian August Friedrich Peters, whose death was mentioned last week, was the son of a merchant at Hamburg, and was born on September 7, 1806. His father's fortunes suffered in the war times, and his son's education was attended with difficulties, though he endeavoured to cultivate to the best of his power the natural bent for mathematical studies which was very early evinced. After some years the attention of Schumacher was drawn to the young Peters, and he employed him in various calculations for his ephemerides and geodetical works, and in 1826, and for several years subsequently, he was actively engaged in such operations at Hamburg and in Holstein, at the same time pursuing his studies and incidental employment under Schumacher. He then became for a time a pupil of Bessel, and in 1834 was appointed assistant in the observatory at Hamburg, whence in 1839 he was promoted to a position in the newly-founded Central Russian Observatory at Pulkowa, where he worked in theoretical and practical astronomy for ten years. In 1849 he was named Professor of Astronomy in the University of Königsberg, where he remained until 1854, in which year he was appointed to succeed Petersen in the direction of the observatory at Altona, and at the same time editor of the *Astronomische Nachrichten*, which he conducted up to the period of his decease. He removed to Kiel when the observatory at Altona was transferred to that place, and died there on the 8th inst., after a severe illness of many months' duration.

The works by which Prof. Peters was perhaps more widely known were his "Numerus constans Nutationis ex Ascensionibus Rectis Stellæ Polaris in Specula Dorpatensi Annis 1822 ad 1838 observatis deductus," which appeared in the *Transactions* of the Imperial Academy of Sciences of St. Petersburg in 1842, and the "Recherches sur la Parallaxe des Etoiles Fixes," printed in the same *Transactions* in 1846. For these important

memoirs he received the gold medal of the Royal Astronomical Society at the hands of Prof. J. C. Adams in 1852. His researches on the proper motion of Sirius also attracted much attention, and many other papers on various astronomical and mathematical subjects were contributed by him to the Altona journal. His later work at Altona and Kiel chiefly bore upon the determination of differences of longitude; the last, "Altona-Göttingen," is to be detailed in a memoir to be published in a few weeks.

MINOR PLANETS.—Circular No. 136 of the *Berliner Astronomisches Jahrbuch* notifies the re-observation of *Hilda*, the most distant of the group of small planets yet known to us, and one which, with *Ismene* No. 190, must at times experience considerable perturbations from the action of Jupiter. It has been found at Pola as an object of 13·5 m., many degrees from the position assigned in the ephemeris last published, but there seems reason to suspect error of calculation. Thus if the elements of Dr. Kühnert in the *Berliner Jahrbuch* for 1880 are employed, though there is a later orbit, the error of the computed place is much less than that shown by the ephemeris in the Berlin Circular, No. 135. The difference of positions appears to indicate that the true period of revolution is even longer than has yet been calculated.

In the same Circular, No. 136, are new elements of *Philomela*, attributing to that planet an almost circular orbit, the angle of excentricity being only 0° 18′ 36″·8, so that $e = 0{\cdot}005414$, which is less than in the case of *Venus*.

Medusa, to which has been assigned the shortest period of any of the minor planet group, has apparently passed the last opposition without being re-observed, but in addition to much uncertainty as to position, it was likely to fall in a region of the sky which is crowded with small stars, and therefore a search would be attended with much trouble and difficulty.

Vesta should now be well discernible without the telescope, being in opposition and perihelion this year nearly at the same time, as we have before remarked, magnitude 5·9. The planet is in perihelion on May 28.

COMET 1880, II.—The following ephemeris is calculated from elements depending upon observations to May 8:—

12h. G.M.T.	R.A. h. m. s.	Decl. ° ′	Log. distance from the Earth.	Log. distance from the Sun.
June 1	6 29 32	+51 38·8	0·4108	0·2683

PHYSICAL NOTES

PROF. LEMSTRÖM, of Helingsfors, has recently described to the Physical Society of St. Petersburg a singular experiment which, unless otherwise explained by some of the circumstances of the experiment not yet published, must be regarded as a fundamental fact in the physical theory of electricity. He finds that a ring of insulating material when rotated about its axis of symmetry with a high velocity acts like a galvanic circuit, and produces a magnetic "field" in the space within it. Prof. Lemström is a disciple of Edlund, and regards this experiment as confirmatory of Edlund's theoretical views on the nature of electricity. According to Lemström, the ether in the insulator, being dragged along by the ring, produces vortical motion of the ether in the central space, which vortical motion he conceives to be the essential condition of a magnetic field. Arguing from these premises, Lemström proceeds to build up an ingenious theory of terrestrial magnetism. The converse operation of rotating an iron bar within a hollow insulating body or insulating medium ought also to produce magnetism in the bar. The earth being a magnetic body rotating in an insulating medium, ought to be magnetised by rotation about its axis, the axis being the axis also of magnetisation, unless the irregular internal disposition of the magnetic constituents produced an irregular distribution of the magnetism, or unless the distribution were affected by the induced magnetism due to movements of electricity in the atmosphere, as in the *aurora*, or by the magnetism which would, on Lemström's theory, be generated by the revolution of the earth round the sun, and by the motion of the solar system through space.

M. DUMAS, who has been examining the property of certain metals in occluding gases, has found that aluminium may occlude as much as one and a half times its bulk of hydrogen gas, and also shows traces of carbonic acid. The gases were given up when the metal was heated to redness under exhaustion. Magnesium behaves similarly. Were these metals distilled *in vacuo* they could probably be obtained pure. It is possible that these observations may throw some light on the anomalous behaviour of aluminium when used as an electrode in the voltameter.

THE cone of rays entering the eye from a peripheric point is never again united to one point, but it must present somewhere a minimum of cross section. The geometrical place of this minimum of cross section Herr Matthiessen (*Arch. f. Ophthalm.* (4) 25, 1879) designates the "theoretic retina." He finds that it is a spherical surface, the middle point of which coincides with the middle point of the corneal ellipsoid. To a distance of 75° from the fovea centralis the theoretical retina corresponds very exactly to the actual (according to the determinations of Arlt and Helmholtz). At greater distances the retina is formed hypermetropically, and so is within the "theoretic retina."

THE influence of magnetisation on the tenacity of iron has been lately studied by Signor Piazzoli (of the Catanian Academy of Sciences). Iron wires were hung between two hooks and ruptured by pouring water into a vessel suspended from them. They were about 350 mm. long, and were inclosed in a spiral with four windings one over another, which were either all traversed by a current in one direction, or two by a current in one direction, and two by an equal opposite current, so that in both cases the wires were equally strongly heated by the spiral, but in one case they were magnetised, in the other not. The weights required to break wires annealed in charcoal (weight of one metre, G = 0·299) were, during magnetisation, P = 1260–1306; without magnetisation, P′ = 1213–1270. In the case of wires annealed in carbonic oxide (where G = 0·46 g.), P = 1732·4 – 1742·7; P′ = 1703·62 – 1719·87. In the case of wires annealed in hydrogen P = 1289·5 – 1310·1; P′ = 1263 – 1299·7. In each separate series, accordingly, the difference P – P′ was frequently less than the difference between the highest and lowest weights required for rupture of apparently identical wires; *still, the mean values in each of the* (14) *series*, were from about 1 to 3 per cent. greater for the magnetised than for the unmagnetised wires, showing that the tenacity of iron increases on magnetisation. This, it is remarked, need not be attributed to a change of cohesion of the iron, but may be due to ordinary magnetic attraction of the successive parts of the wires. In eleven out of fourteen cases the relative elongation of the magnetised wires at rupture was greater than that of the unmagnetised, in three cases less.

IN a recent note to the Vienna Academy, Prof. Ludwig gives the results of the first of a series of observations on the decomposition of organic compounds by zinc powder. This relates to alcohols, and it is stated that in distillation of these over zinc powder heated to 300 – 350° C., the higher ones—from ethylic alcohol upwards—are split up into the corresponding olefine and hydrogen. Under the same conditions methylic alcohol is decomposed simply (if the small quantities of marsh gas be neglected) into carbonic oxide and hydrogen. The similar decomposition of ethylic alcohol into marsh-gas, carbonic oxide and hydrogen, only occurs at a considerably higher temperature —with dark red glow. On the ground of these decompositions, which indicate that the combination of the carbon and the oxygen must be a very strong one, it is supposed that the decomposition of the higher alcohols is no simple reduction to the saturated hydrocarbons, from which, then, by separation of hydrogen, the olefines might arise, but that in the first phase of the process the alcohol is split up into the olefine and water, and that the hydrogen concentrated in the gases is due to a reduction of the generated steam by the zinc powder.

PROF. RIGHI has recently described to the Bologna Academy an arrangement of Holtz's electric machine, in which the whole machine except the handle and the electrodes is inclosed, along with a small friction machine for excitation, in a glass case tightly

closed by means of strips of fur, and dried interiorly with chloride of calcium, so that in all weathers the machine acts well.

HERR ZEHFUSS has lately given (*Wied. Ann.*, 4) some personal experiences of the phenomenon of "after images of motion" (about which Plateau and Oppel have before written). These after images may be had, *e.g.*, in a train, if one look at a point on the horizon for a little, then turn to look at (say) a horizontal fibre in the wood of the carriage, or close one's eyes. Motions then seem to be still perceived; in the latter case, *e.g.*, a stream of sparks seems to be moving to the right (or if the point originally looked at have been between the observer and the horizon, there is a stream of sparks above going to the right and one below to the left). Herr Zehfuss offers a physiological explanation, in preference to the partly psychical ones proposed by Plateau and Oppel. Each individual nerve rod, he supposes, has special blood-vessels, which, when the original image of a moved object goes to the right, directs the course of the blood to that side, just as in ordinary light the decomposed blood is promptly replaced by fresh. By this preponderant direction of blood to the right a heaping up occurs in each retinal element on the right, which gives rise to return currents as soon as the outer cause has ceased to act. As the blood flows back there arise, in consequence of the specific excitability of the rods, those spark-streams, which are projected as elementary motions to the right.

IN a recent number of *Wiedemann's Annalen* (3) Herr Schönn describes a method of making visible ultra-violet prismatically decomposed light in such a way that exact measurements can be made. One feature of it is the use of a disk of fine calking paper saturated with sulphate of quinine, and contained in a small cell which is brought close before the Ramsden ocular, which can be directed at once on the disk and on a luminous line (its axis is not inclined like that of Soret's, but coincides with the axis of the telescope). The author gives measurements of the ultra-violet spectrum of cadmium, zinc, and thallium.—In the same number Herr Glan describes a "spectro-telescope," with which objects can be seen in any homogeneous colour at will. The instrument has various applications, especially in astrophysics.

IN a paper on the thermic theory of the galvanic current (*Wied. Ann.*, No. 4) Herr Hoorweg lays down the following propositions:—Wherever two conductors come into contact, motion of heat results in development of electricity; therefore a constant electric difference arises between the two substances. 2. If in a closed circuit, the total sum of the differences of potential be different from zero, there arises in this circuit a continuous electric current. 3. This current exists at the cost of the heat at one part of the point of contact, and has heat-production in the other for a result. 4. All voltaic currents are thermo-currents. 5. The chemical action in the battery and the decomposition apparatuses is a result of the galvanic current.

AN interesting series of experiments has been recently made by Dr. König on the vibrations of a normal tuning-fork (*Wied. Ann.*, No. 3). He finds that, practically, at least to 50° to 60° of heat, the influence of heat on a tuning-fork may be regarded as constant. Thick tuning-forks are more affected by heat than thin ones of the same pitch, indicating (it is remarked) that change of elasticity, and not change of the length of the arms, is the primary cause of the change of pitch. The influence of heat on tuning-forks of different pitch, and of not very different thickness, is proportional to their number of vibrations. Generally the period of vibration of a tuning-fork is increased or diminished $\frac{1}{8910}$ by a difference of temperature of 1° centigrade. The general change in pitch of the normal fork $Ut_3 = 512$ vibrations per second at 20°, through the temperature difference of 1° C. is 0·0572 vibrations per second. Dr. König has constructed a fork which, at any temperature, will exactly give 512 vibrations.

SOME quotations by Herr Oehler (*Wied. Ann.*, No. 3) from Jacob Hermann's work, "Phoronomia sive de Viribus," &c., published in 1716, have a curious significance in relation to the history of the mechanical theory of heat. In the twenty-fourth chapter, "De motu intestino fluidorum," the following paragraph occurs:—"Hoc nomine non intelligitur hoc loco internus molecularum motus fluidi cujuscunque in suo statu naturali consistentis, sed is particularum motus, qui in fluidis a causis externis et accidentalibus excitari solet, quo calor præsertim est referendus, qui dubio procul ex concitatiore particularum motu in corpore calido a causis externis producitur. Utut vero ejusmodi motus intestinus admodum perturbatus sit, nihilo tamen minus regula physice satis accurata pro ejus mensura media tradi potest. In another place Hermann offers a demonstration of the theorem that "Calor, cæteris paribus, est in composita ratione ex densitate corporis calidi, et duplicata ratione agitationis particularum ejusdem."

GEOGRAPHICAL NOTES

LIEUT. A. LOUIS PALANDER, of the Swedish Royal Navy, was last week elected a Corresponding Member of the French Geographical Society, in acknowledgment of his brilliant services to geography as commander of the *Vega* during the late Arctic Expedition. We understand that the Swedish Royal Academy of Sciences have just caused a handsome bronze medal to be struck in commemoration of the successful accomplishment of this enterprise. This medal shows on one side the heads of Prof. Nordenskjöld and Lieut. Palander, and on the other a well-executed representation of the *Vega* surrounded by ice.

AT the Anniversary Meeting of the Geographical Society, on Monday next, the Earl of Northbrook will take the chair for the last time, and will deliver an address on recent geographical progress. The formal presentation of the Royal Medals will also take place at this meeting, though neither of the recipients (Lieut. Palander and Mr. Ernest Giles) can be present. The Duke of Edinburgh, Honorary President of the Society, will preside at the Anniversary Dinner in the evening, which will be held, as usual, at Willis's Rooms.

LORD ABERDARE, it is understood, will succeed the Earl of Northbrook as President of the Geographical Society.

A BEGINNING is about to be made to carry out Lieut. Weyprecht's proposal for a circle of observing stations around the North Polar region. The Danish Government has resolved to establish a station at Upernivik, in West Greenland; the Russian Government has granted a subsidy for an observatory at the mouth of the Lena, and another on the new Siberian Islands; Count Wilczek is to defray the expenses of a station on Novaya Zemlya under the direction of Lieut. Weyprecht; the U.S. Signal Service, under General Myer, has received permission to plant an observatory at Point Barrow, in Alaska; and it is expected that Canada will have a similar establishment on some point of her Arctic coast. At the Hamburg Conference it was announced that Holland would furnish the funds for a station in Spitzbergen; and it is expected that Norway will have an observing post on the extremity of the Province of Finmark. This is a good beginning, and we hope that some sort of agreement will be established to have all the observations made after a uniform method, otherwise their value will be greatly decreased.

BARON EGGERS, of St. Thomas, West Indies, sends us a prospectus of a plan for the scientific exploration of the West Indies, especially as regards their natural history, his main purpose evidently being to make complete collections of plants, insects, and shells. Such collections he offers at certain rates to all who express their wish to become subscribers, the subscription to be paid on delivery of the collections. Details may be obtained from Baron Eggers or from his agent in Europe, Dr. Eug. Warming, Copenhagen.

M. PAUL SOLEILLET, who was compelled to return to Senegal in his attempt to reach Timbuctoo, is now in Paris, and expresses his determination to embark again in July, to make another attempt.

A SOCIETY of Geography for the north of France has been established at Douai.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The election to the Professorship of Mineralogy, vacant by the death of Dr. W. H. Miller, F.R.S., will be held in the Senate House on June 12.

In the fourteenth Annual Report of the Museums and Lecture-Room Syndicate, Lord Rayleigh, the recently-appointed Professor of Experimental Physics, says:—"On visiting the Cavendish Laboratory in December last, after my appointment to the Professorship of Experimental Physics, I was at once struck with the

great deficiency of apparatus. The building itself appears to me to be very convenient and adequate to its purpose, but the advantages which it should afford cannot be fully realised without a large addition to the existing stock of apparatus. Even with an adequate outfit, a considerable annual expenditure is necessary for renewals and to meet the wants of students engaged in original research. Knowing that the University is not likely for several years to be in a position to meet the want, and feeling that Cambridge ought not to remain in this respect behind several Continental and American Universities, I have been endeavouring to raise an apparatus fund, to be spent in eight or ten years at the discretion of the Professor, by inviting contributions from persons interested in Cambridge and in science. I have been fortunate enough to secure the co-operation of the Chancellor, to whom the University is already indebted for the building and for most of our existing apparatus; and the proposal has met with such a degree of support from others that it may be considered to be already a partial success. It is difficult to form an exact estimate beforehand, but I should suppose that 2,500*l.* will be required during the next ten years to put the institution upon a proper footing." Lord Rayleigh announces that he has received promises and donations amounting to 1,825*l.*

In connection with the Science and Art Department at South Kensington the following courses of instruction for science teachers will probably be organised this summer:—(1) Chemistry, from July 7 to 29, Dr. W. R. Hodgkinson. (2) Light, from June 29 to July 14; (3) Magnetism and Frictional Electricity, from July 15 to 30, Prof. Guthrie, F.R.S. (4) Applied Mechanics, from June 30 to July 22, Prof. Goodeve, M.A. (5) Geology, from June 30 to July 22, Prof. Judd, F.R.S. (6) Botany, from July 7 to July 29, Prof. W. T. Thiselton Dyer, F.R.S.

SOCIETIES AND ACADEMIES

London

Royal Society, May 13.—Abstract of paper "On the Chemical Composition of Aleurone-Grains," by Dr. Vines.

This paper continues the account of this investigation, which appeared in the *Proceedings* for 1878. It was therein shown that the aleurone-grains of the Lupin consist of three proteid substances, namely, of two globulins—the one belonging to the myosin group, the other to the vitellin group—and of a substance, allied to the peptones, provisionally termed hemialbumose. In the present communication the results of the investigation of the grains of the peony and of the castor-oil plant (*Ricinus*) are given. The grains of the peony are found to be readily soluble in distilled water. Treatment with 10 per cent. NaCl solution, however, proves the existence of a myosin-globulin. Apparently no vitellin-globulin is present. The grains contain hemialbumose in considerable quantity. The grains of Ricinus present a complex structure. They consist of a mass of ground-substance of proteid nature, inclosing a crystalloid of proteid substance and a globoid which consists of inorganic matter. The ground-substance is found to be composed, like the grain of the Lupin, of the two globulins and of hemialbumose. The chemical nature of the crystalloid is not so clearly made out. It is slowly soluble in 10 per cent. NaCl solution, and readily soluble in 20 per cent. or in saturated NaCl solution after treatment with alcohol. The crystalloids of several plants were investigated with the view of ascertaining their relative solubility in solutions of this salt. Those of *Viola elatior* and of *Linum usitatissimum* were found to resemble those of Ricinus in this respect; those of Bertholletia and of Cucurbita are readily soluble in 10 per cent., and saturated NaCl solutions; those of *Musa ensete* and *hillii* and those of *Sparganium ramosum* are either insoluble or only partially soluble in these solutions.

The points of more general interest are the action of alcohol in promoting the solution of the crystalloids of Ricinus in 20 per cent. and in saturated solutions of NaCl, and the fact that long-continued exposure to alcohol does not render the vegetable globulins insoluble in these solutions.

The author finally expresses his opinion that the caseins which Ritthausen has extracted from various seeds consist to a considerable extent of precipitated hemialbumose.

Physical Society, May 8.—Sir William Thomson, president, in the chair.—New Members: E. F. Bamber, Dr. E. Obach, R. D. Turner, E. Woods, H. E. Roscoe, H. Watts.—Prof. Minchin, of Cooper's Hill Engineering College, described his further researches on the subject of photoelectricity, brought by him before the last meeting of the Society. He has found that the current in a sensitive silver cell does not always flow from the uncoated to the coated plate. It does when chloride or bromide of silver is used, but when the sensitive emulsion is iodide of silver and the liquid water tinctured with iodide of potash, the current is from the coated to the uncoated plate. He demonstrated that the current set up by the fall of light on the cell could be sent by wire to a receiving cell, and made to produce a *local* effect on the sensitive plate therein. He also proved that electricity is developed in fluorescent bodies by the action of light, and hopes to show that it is also developed in phosphorescent bodies. Neither heat nor the red rays produce this electricity, but it is the blue and violet rays which do so. The fluorescent silver plates he employed were coated with an emulsion of eosine and gelatin, and had been kept sensitive for twelve days. They would thus be a permanent source of photoelectricity, did the eosine not tend to leave the gelatin. Mr. Wilson had suggested naphthaline red for eosine, as not apt to leave the gelatin, and he had found it give good results.—Dr. O. S. Lodge described certain improvements which he had made in his electrometer key designed for delicate electrical and especially electrostatic experiments. Assisted by the British Association, he had made it more convenient, and fitted it into an air-tight case which could be artificially dried. The contact-pins were now of phosphor-bronze gilt instead of platinum, and the contacts were made by press-pins from the outside. Dr. Lodge also exhibited a new inductometer or modified form of Prof. Hughes's induction balance, conbining a Wheatstone balance, and expressly designed for comparing capacities and resistances, especially the resistances of coils having no self-induction. A telephone takes the place of a galvanometer in the bridge, and the current in the primary coil is interrupted by a clockwork make and break. There is one primary coil of fine wire $3\frac{1}{2}$ ohms in resistance and two secondaries, one on each side of it, of fine wire, each about 270 ohms. These are fixed, but the primary is adjustible by a screw. Prof. Hughes remarked that he had pointed out in his paper to the Royal Society that the induction-balance could be used in this way; and Dr. Lodge disclaimed any novelty in the apparatus beyond its arrangement. Sir W. Thomson added that it was satisfactory to see so serviceable an adaptation of the induction-balance to research.—Dr. Hopkinson, Prof. Perry, and Sir W. Thomson offered remarks on the element of time in comparing discharges from condensers of different dielectrics. Sir William said that, in 1864, he had made experiments on air and glass dielectrics, and found the discharge about the same for the first quarter-second.—Prof. Adams then took the chair, and Sir. W. Thomson made a communication on the elimination of air from a water steam-pressure thermometer, and on the construction of a water steam-pressure thermometer. He said it was a mistake to suppose that air was expelled by boiling water, because the water dissolved less air when warm than when cold. The fact was due to the relations between the density of air in water and the density of air in water vapour. There was fifty times more air in the water vapour over water in a sealed tube than in the water below. If this air could be suddenly expelled only $\frac{1}{50}$th part of air would remain, and of this only $\frac{1}{2500}$ in the water, the rest being in the vapour. This suggested a means of eliminating air from water, whichhe had employed with success. It consisted in boiling the water in a tube, and by means of a fluid mercury valve allowing a puff of the vapour to escape at intervals. Sir W. Thomson also described his new water-steam thermometer now being made by Mr. Casella. It is based on the relations of temperature and pressure in water-steam as furnished by Regnault's or other tables, and will consist of a glass tube with two terminal bulbs, like a cryophorous, part containing water, part water-steam, and the stem inclosed in a jacket of ice-cold water. Similar vapour-thermometers will be formed, in which sulphurous acid and mercury will be used in place of water, or in conjunction with it. For low or ordinary temperatures they will be more accurate than ordinary thermometers.

Geological Society, May 12.—Robert Etheridge, F.R.S., president, in the chair.—Rev. Samuel Gasking, Thos. J. George, and Cuthbert Chapman Gibbes, M.D., were elected Fellows of the Society.—The following communications were read:—On the structure and affinities of the genus *Protospongia*, Salter, by W. J. Sollas, F.G.S.—Note on *Psephophorus polygonus*, von Meyer, a new type of Chelonian reptile allied to the leathery

turtles, by Prof. H. G. Seeley, F.R.S.—On the occurrence of the Glutton (*Gulo luscus*, Linn.) in the forest-bed of Norfolk, by E. T. Newton, F.G.S. Remains of the Glutton have hitherto been obtained only from cave-deposits. The author has lately received from Mr. R. Fitch, of Norwich, a portion of the lower jaw of this animal obtained from the forest-bed of Mundesley, Norfolk. The specimen consists of about two inches of the left ramus, bearing the first true molar and the hinder half of the fourth premolar in place. The jaw is smaller than in average specimens of the recent Glutton, but presents all the characters of the species as described in detail by the author.—A review of the family Diastoporidæ, for the purpose of classification, by George Robert Vine. Communicated by Prof. Duncan, F.R.S. —On annelid jaws from the Wenlock and Ludlow formations of the West of England, by G. J. Hinde, F.G.S.

Entomological Society, May 5.—H. T. Stainton, F.R.S., vice-president, in the chair.—Mr. Peter Inchbald, of Hovingham, York, was elected a member of the Society.—Mr. W. C. Boyd exhibited a very pale specimen of *Nyssia hispidaria*, taken at Cheshunt.—Mr. M. J. Walhouse exhibited some Geodephagous beetles, which were found only on the summits of some of the highest mountains in India.—Mr. W. L. Distant exhibited a long series of specimens of the Madagascar homopteron *Ptyelus goudoti*, Benn., to illustrate the extreme variability of the species. The series showed a gradation from melanic to albinic forms, and one specimen was asymmetrical in the markings of the tegmina, thus exhibiting the characters of two varietal forms, an occurrence which Mr. Distant stated was not altogether exceptional in extremely variable species of the order Rhynchota.—Mr. T. R. Billups exhibited two living specimens of *Carabus auratus*, which had been found in the Borough Market. In reference to a prediction by Mr. Wallace that a sphinx moth would be found in Madagascar with a proboscis of sufficient length to reach into the nectary of *Anagræcum sesquipedale*, Mr. Pascoe stated that he had heard a rumour that such an insect had been discovered, and endeavoured without success to find any corroboration of the statement from members of the Society. —Miss E. O. Ormerod made some remarks as to the contents of a work which she had edited and presented to the Society, and which contained the meteorological observations taken by Miss Molesworth for a period of forty-four years. Some attempt was made to contrast the meteorological conditions with the dominant phases of plant and animal life during that period.

Victoria (Philosophical) Institute, May 10.—A paper upon the data of ethics, with special reference to Mr. Herbert Spencer's views, was read by Prof. Wace.

PARIS

Academy of Sciences, May 17.—M. Edm. Becquerel in the chair.—The President presented the new edition of the works of Laplace, with letter from Laplace's granddaughter.—The following papers were read:—Meridian observations of small planets at the Greenwich and Paris observatories during the first quarter of 1880; communicated by M. Mouchez.—On saccharine, by M. Peligot. It is dextrogyrous, like ordinary sugar; its rotatory power, in Laurent's polarimeter, represented by 93° 5′ (sugar, 66° 18′). Saccharine from starch-glucose, and that from crystallised levulosate of lime, showed the same rotatory power. The essential character of saccharine is its relative stability and its inertia towards agents which act on other matters of the sugar group. It is much more easily got from crystallised levulosate of lime than from inverted sugar or starch-glucose.—Researches on the proportion of carbonic acid in the air; second note by M. Reiset. He made (ninety-one) fresh experiments in the country from June to November last year, day and night, and the average obtained was 29·78 CO_2 in volume, for 100,000 dry atmospheric air at 0° and 760 mm.; (this closely agrees with the figure 29·42 he got in 1872-73). He describes a new absorption apparatus, with the aid of which six or seven hours was sufficient to ascertain the yield of 600 litres of air. 28·91 was the average proportion of CO_2 for the day, 30·84 for the night. The maxima were in times of fog and mist; the average of twelve such cases was 31·66; the absolute maximum, 34·15, in a dense fog on September 3. He questions the accuracy of the method by which MM. Levy and Allaire found variations last year ranging from 22 to 36.—On the Furens dam, by M. de Lesseps. The dam of the Chagres (40 m. high) should be built on this type, and not cost over 25,000,000 fr.—M. Peters' death was announced.—On some nutritive effects of alkaline substances in moderate doses, from experimentation on man in good health, by MM. Martin Damourette and Hyades. The substances tried were bicarbonate of soda (3 gr. daily) and Vichy water from the spring Elizabeth de Cnaset (0·5 to 1 lit. a day). So taken, they are trophic agents, and they diminish uric acid largely (though the former causes gastric disorders).—Position of the comet *b* of 1880, determined at Bordeaux Observatory, by M. Rayet.—On the transcendants which play a fundamental *rôle* in the theory of planetary perturbations, by M. Callandreau.—On the number of cyclic groups in a transformation of space, by M. Kantor.—The tensions of saturated vapours have different modes of variation according as they are emitted above or below the point of fusion, by M. de Mondesir. The passage through the point of fusion always gives a variation at least four or five times greater than that found in two liquids in an equal thermometric range.—On the interversion of temperatures of the air with the height, by M. André. This is shown to occur (under like conditions) within much shorter vertical distances than those indicated by M. Alluard.—On the freezing mixtures formed of an acid and a hydrated salt, by M. Ditte. In such a mixture the cooling is not due to simple dissolution of the salt; there is always a double decomposition, conformably to the law of maximum work. The salt containing much water, this separates out, and the change of state absorbs the heat liberated by the reaction, borrowing from the liquid itself the surplus of energy necessary to its complete accomplishment. Hence results a considerable lowering of temperature.—Influence of alkaline or acid media on the life of crayfish, by M. Richet. Acid or basic liquids are not poisonous in the direct ratio of their acidity or basicity. With equal weight nitric acid is five times more toxical than sulphuric acid, and twenty-five times more than acetic acid. Generally bases have a more hurtful action than acids. The least toxical is baryta; a crayfish will live two or three hours in water containing 3 grs. of it per litre. Soda and lime are fatal in two or three hours in proportion of 1·5 grs. per litre; potash in one of 1 gr. Ammonia, however, is the most poisonous of all; in the proportion of 0·8 gr. per litre, its action is almost instantaneously fatal. It is thirty times more toxical than baryta, and fifteen than soda. —On some of the conditions of cortical excitability, by M. Couty. The movements caused by faradisation of the brain seem to vary like the less complex contractions caused by faradisation of the central end of the sciatic, pointing to a common origin of the two orders of movements in the same bulbo-medullary elements.—Local and general anæsthesia produced by bromide of ethyl, by M. Terrillon. The substance seems especially suited for short operations not requiring complete muscular resolution. It acts rapidly, is less dangerous than chloroform, and the awaking is not disagreeable.—Variations of urea in poisoning by phosphorus, by M. Thibaut.—Influence of the fattening of animals on the constitution of fats formed in their tissues, by M. Muntz. In animals submitted to a fattening process the fat is always poorer in solid fatty matters.—On the fixity of composition of plants; analysis of *Soya hispida*, or Chinese oleaginous pea, by M. Pellet.—On the respiratory and circulatory apparatus of some larvæ of diptera, by M. Viallanes. The heart of insects is at first a simple tube open only at its two ends. So long as it has no lateral orifices it is completely arterial.

SIGN LANGUAGE AMONG THE AMERICAN INDIANS

Introduction to the Study of Sign-Language among the North American Indians, as Illustrating the Gesture-Speech of Mankind. By Garrick Mallery. (Washington: Government Printing Office, 1880.)

UNDER this modest title another of those valuable contributions, which we owe to the Smithsonian Institution, has been made to science. Researches into the ethnography of the North American Indians have been going on for the last eleven years under the superintendence of Mr. J. W. Powell, and a series of compact and beautifully-printed monographs has lately been started for the purpose of aiding and directing them. The monograph just issued forms the second of the series hitherto published, and in spite of its title is full of new and interesting matter. It will be appreciated not only by those who are actually engaged in observing the life and manners of barbarous tribes, but also by every student of language and anthropology.

The evidence that has been accumulating for some time past makes it probable that the most important part of language, its grammatical machinery, originated in gestures and signs. These were the means whereby sense and meaning were imported into spoken words. As Col. Mallery remarks: "A child employs intelligent gestures long in advance of speech, although very early and persistent attempts are made to give it instruction in the latter but none in the former; it learns language only through the medium of signs; and long after familiarity with speech, consults the gestures and facial expressions of its parents and nurses as if to translate or explain their words." An examination of the sign-language or languages of mankind consequently becomes of high importance, and it is strange that no thorough and scientific attempt to undertake it has hitherto been made. Leibnitz indeed, with the instinct of genius, pointed out the need and importance of such an investigation (in his "Collectanea Etymologica," ch. 9), but his words met with no response. It is therefore all the more satisfactory to find that the subject has at last been taken up in America, where special opportunities still exist for collecting materials, notwithstanding the rapid decrease in the native population that seems to have been going on of late years. North America has always been the country where a language of signs was pre-eminently in vogue. Col. Mallery says with justice that "the words of an Indian tongue, being synthetic or undifferentiated parts of speech, are in this respect strictly analogous to the gesture elements which enter into a sign-language." Just as a single idea or mental picture is represented by a connected group of individual gestures, so too it is expressed in the polysynthetic speech of the Red Indian by a group of individual syllables which form but one word.

The first question we have to ask ourselves is whether sign-languages are the same all over the world, whether each idea or group of ideas has a fixed and natural gesture or sign corresponding to it everywhere. To this question the researches made among the American Indians furnish a conclusive reply. "The alleged existence of *one* universal and absolute sign-language is, in its terms of general assertion, one of the many popular errors prevailing about our aborigines." Many signs are purely conventional, while many ideas or objects may be denoted by more than one sign. The signs used by the different Indian tribes to indicate the same ideas by no means agree together, nor do they always agree, so far as I know, with the signs employed for the same ideas in the Old World, whether by savages or by deaf-mutes. The curious language of signs employed in monasteries where the rule of silence was strictly observed, which is given by Leibnitz, if compared with the lists of signs furnished by American explorers, is a good example of the fact.

At the same time no signs can be so arbitrary and conventional as spoken words, nor can an idea be expressed by so many different signs as it can be by different sounds. Col. Mallery observes that "further evidence of the unconscious survival of gesture-language is afforded by the ready and involuntary response made in signs to signs when a man with the speech and habits of civilisation is brought into close contact with Indians or deaf-mutes. Without having ever seen or made one of their signs, he will soon not only catch the meaning of theirs, but produce his own, which they will likewise comprehend, the power seemingly remaining latent in him until called forth by necessity. The signs used by uninstructed congenital deaf-mutes and the facial expressions and gestures of the congenitally blind also present considerations under the heads of 'heredity' and 'atavism,' of some weight when the subjects are descended from and dwell among people who had disused gestures for generations, but of less consequence in cases such as that mentioned by Cardinal Wiseman of an Italian blind man who, curiously enough, used the precise signs made by his neighbours."

But care must be taken to distinguish between two things which are frequently confused together. Gestures and signs are wholly different, gestures being natural signs more or less conventional. A gesticulation is a gesture which has become a sign, and the nearer signs approach to gesticulations the more readily and instinctively they will be understood.

Those who wish to know what the Indian sign-language is will find plenty of interesting and suggestive examples in Col. Mallery's *Introduction*. He has added a list of his authorities as well as a speech in signs addressed by a medicine-man of the Wichitas to Mr. A. J. Holt, and a story in signs told by Natshes, the Pah-Ute chief, to Dr. W. J. Hoffman. These curious specimens of sign-language will show what it is more effectually than any description could do, and will justify the analysis and classification of the signs proposed by Col. Mallery.

In conclusion, aid and suggestions are asked from all interested in the subject, or who are in actual contact with savage and barbarous tribes. A list of words is appended for which the corresponding signs are wanted, those of chief importance being marked by an asterisk. We hope that the ethnographical department of the Smithsonian Institution will meet with all the assistance in this undertaking to which it is entitled. There must be many observers among the uncivilised races of the Old World

or in schools for deaf-mutes who have many facts of interest and value to contribute. It is only when these facts have all been gathered in that it will be possible to reconstruct that primitive speech of mankind which preceded articulate utterance, which formed the bridge to spoken language and expressed the earliest thought of the human race. A. H. SAYCE

TESTING TELEGRAPH LINES

Instructions for Testing Telegraph Lines and the Technical Arrangement of Offices. By Louis Schwendler. Vol. ii. Second Edition. (London: Trübner and Co., 1880.)

THE second volume of this useful work is free from the defects which disfigured the first volume, and which we were bound to find fault with (NATURE, vol. xix. p. 192). This is doubtless due to the watchful eye and careful hand of Prof. M'Leod, who has nursed it through the press and added some useful notes. It contains a very full and clear description of Mr. Schwendler's modification of the tangent galvanometer, by which quantitative electrical measurements of batteries, lines, and apparatus are more rapidly though more roughly made than with bridges and coils. Such an instrument is very extensively employed in England and America, but Mr. Schwendler has certainly improved its efficiency by combining certain resistances with it and making it more portable. It is remarkable what a handy and useful instrument this becomes, and what a valuable help it is to the telegraph engineer. Mr. Preece mentioned at the Society of Telegraph Engineers the other evening that it frequently happened over the extensive system of the Post Office—120,000 miles of wire and 12,000 instruments—that the daily bill of health showed not one single fault existing, and this he attributed principally to that accurate system of testing which has been in use in England for nearly twenty years. Mr. Varley introduced this system in England and in America also, where it is very extensively employed. It is a pity that Mr. Schwendler has not made himself better acquainted with the systems in use in other countries, for the perusal of his book leaves the impression that he thinks he has inaugurated a new system in India, whereas he has only modified existing systems to suit the requirements of the Indian service. Again this desire to be individual is shown by the adoption of that most unnecessary nomenclature of unit current, the "Oersted." Unit current is now universally known as the "Weber," and though some confusion has occurred as to whether unit current should be "webers per second," or simply "weber," nevertheless "webers" and that useful sub-multiple "milliwebers" are now used all over the world, except in India. Custom only has forced the terms *volt*, *ohm*, *farad*, *weber* into use. He would be a bold man who would attempt to convert "Ohm" into "Schwend," yet Mr. Schwendler would convert "Weber" into "Oersted." There is no doubt that Mr. Latimer Clark, who is the author of the recognised nomenclature, proposed the term "weber" for unit quantity, but as any term applied to unit quantity, excepting that based on unit capacity or "farad," is not wanted, and unit current is unit quantity per unit time, "webers per second" has rapidly, by the silent linguistic process of abbreviation, subsided into "webers," and webers it will remain. This strange habit of ignoring existing terms is shown in the definition of "intensity" (p. 40) as applied to a battery which is said to be the maximum current which a battery produces on short circuit. Now there is scarcely an English-speaking country where this property is not known as "quantity," though this term is carefully excluded from all books from its eminently unscientific character. Nevertheless it is so rooted in telegraphic circles that there is scarcely a lineman in all England that does not use it. Again, those currents which every one knows as "earth currents" are called in India "natural currents" (p. 53). Moreover we have the strange anomaly that sometimes the author uses *Siemen's units*, sometimes *ohms*, sometimes *S.U.*, and sometimes *B.A.U.*, to designate units of resistance.

The battery used in India is the Minotto form of Daniell—a very wasteful cell, and giving for line purposes an internal resistance of 30 ohms! In dry climates where the circuits are long such a battery may be useful, but in damp climates, like England, where the circuits are comparatively short, such a battery is impossible. The Minotto cell is, however, very constant in its electromotive force; and Mr. Schwendler's instructions for its maintenance are very clear and complete.

The principal portion of the book is devoted to a description and mode of construction and examination of the instruments in use in India and their connections. Mr. Schwendler has introduced a useful test called the "range test," by which those currents are recorded between which the instrument will work without any re-adjustment. Thus the range test of a Siemen's relay is 25. In other words, whether the current used be ·001 or ·025 weber, or any current of intermediate strength, the relay will equally work. An instrument that will stand such a test must be quite free from friction in its points or from residual magnetism in its iron core. The working currents in India never exceed 8 milliwebers nor fall below 2 milliwebers. Hence if a relay fulfil the above test it never wants adjustment. This is certainly "a consummation devoutly to be wished" by all telegraphists.

We observe the following interesting instruction: "On no account are relays to be exposed to the direct rays of an Indian sun. The permanent magnet is sure to lose its magnetism perceptibly, and consequently the relay will become unsensitive." Is this due to the light or to the heat of the sun? His notions of the efficiency of lightning protectors are rather heterodox. "All," says he (p. 195), "that can be said of them at present is, that if they are kept clean they do no harm;" yet he gives a very clear description of those in use. He attributes to Steinheil, in 1846, the first lightning discharger; but Highton, on the London and North-Western Railway, before this, rapt the wire for eight inches on each side of the instrument in bibulous paper and surrounded it with a mass of metallic filings placed in a tin lined box in connection with the earth.

Very excellent descriptions are given of different forms of relays and of various plans devised for reducing the effects of induction, notably Mr. W. P. Johnston's electro-magnetic shunt. Indeed the work is an admirable description of telegraphy in India, and it is one which should be in every electrician's library. There are

many telegraph administrations which would be benefited by its clear practical character. But it is not immaculate. The chief defect of the book is the absence of recognition of what has been done elsewhere and the negation of existing literature dealing with the same subject. Mr. Latimer Clark's book on "Electrical Measurement" (published in 1868) was written especially for use in India. His "Electrical Tables and Formulæ," written in conjunction with Mr. Sabine and published in 1871, contains nearly all that is known of testing. Culley's "Handbook," first published in 1866, has run through six editions. Hoskiær's "Guide to Electric Testing" was published in 1873, and has reached a second edition. Preece and Sivewright's "Text-book of Telegraphy" was published in 1876, and has also reached a second edition. Kempe's "Handbook of Electric Testing" (a most useful and valuable little work) was also published in 1876. Papers by Fleeming Jenkin, Siemens, F. C. Webb, Hockin, Heaviside, &c., are scattered everywhere; yet the impression left on the mind after perusing Mr. Schwendler's book is that, according to him, there is but one system of testing, and that is to be found in India; and there is but one book on the subject, and here it is!

OUR BOOK SHELF

A Physical, Historical, Political, and Descriptive Geography. By Keith Johnston, F.R.G.S. Maps and Illustrations. (London: Stanford, 1880.)

THIS work is in every way creditable to its unfortunate young author, who, our readers may remember, succumbed some months ago to the hardships of African travel while leading an expedition from the West Coast towards Lake Tanganyika. Mr. Johnston has not sought to enter into that minute and often painful detail with which we are familiar in most text-books of geography. His object has been to record in each of the great departments of geography the results of the latest research, leaving it to the teacher or to special text-books to fill up with details. After a brief sketch of some of the main points in mathematical geography, a clear and sufficiently full sketch of historical geography is given, treating not merely of the progress of discovery, but of the various movements of peoples and nations which have led up to the political divisions of the earth as they are at present; this we think a useful introduction of scientific method into history. Then follows a section on physical geography, in which the most trustworthy results of research in the various departments of this subject are stated with clearness and accuracy. The remaining two-thirds of the work is devoted to the special geography of the various continents and countries—their physical features, natural history, products, industries, peoples, and political and social conditions. The same method is followed throughout of dwelling only upon the important features. The work is amply illustrated by useful and beautifully executed maps, and is one of the best general handbooks of geography that we know.

Zeitschrift für das chemische Grossgewerbe. iv. Jahrgang. Von Jul. Post. Fortgesetzt von Arthur Lehmann. (Berlin: Oppenheim, 1880.)

WE have already had occasion to draw attention to the merits of this publication, and the present issue of the work is in no way inferior to its predecessors. It constitutes a complete compendium of the progress of chemical technology during the past year, and as such must be of great service to our manufacturers. The various articles are contributed by acknowledged authorities, and the whole is preceded by a short review indicating the more striking improvements which have been introduced into the chemical arts since the publication of the last issue of the work.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Lesser Spotted Woodpecker

I HAVE had an opportunity lately of observing closely the habits of the Lesser Spotted Woodpecker (*Picus minor*) as regards the very peculiar sound which it makes upon trees by the action of its bill.

It is quite certain that this habit has nothing whatever to do with the quest for food. The bird selects one particular spot upon the trunk or bough of a tree, which spot is naturally sonorous from the wood being more or less hollowed by decay. The bird returns to this precise spot continually during the day and produces the sound by striking the wood on the spot with its bill, the stroke being repeated with a rapidity which is really incomprehensible; for it quite eludes the eye. It is effected by a vibratory motion of the head; but the vibrations are so quick that the action looks like a single stroke. After short pauses this stroke is again and again renewed, sometimes for several minutes together. During each interval the woodpecker looks round it and below it with evident delight and with an apparent challenge of admiration. The beautiful crimson crest is more or less erected.

The whole performance evidently takes the place of the vernal song in other birds; and so far as I know it is the only case among the feathered tribes in which vocal is replaced by instrumental music.

The nest does not appear to be in the same tree; but similar spots are selected on several trees in the neighbourhood, and as the sound is very loud and is heard a long way off, the hen bird when sitting is serenaded from different directions.

I have not seen or heard any attempt to vary the note produced by variations either in the strength or in the rapidity of the stroke, or by changing the point of percussion; but I have observed that the note varies more or less with the tree on which it is produced.

During about six weeks the performance has been frequent every day, and early in the mornings during part of this time it was almost constant. Of late it has been discontinued. In all probability this is parallel to the well-known fact that singing birds cease to sing after the eggs are hatched.

This instrumental substitute for singing among the woodpeckers is extremely curious. ARGYLL

Mr. Preston on Vortex Atoms

SOME passages in an article in NATURE, vol. xxii. p. 56, on Sir William Thomson's theory of vortex atoms, seem to show that the author, Mr. Preston, has not perfectly apprehended the nature of vortex motion. On p. 57 he says that "the rotating portion" of the liquid "therefore glides smoothly over the incompressible liquid that surrounds it like a pipe." From this it appears that the vortically-moving fluid is conceived by him as slipping with reference to the rest of the fluid. This is, however, an incorrect view of the nature of the motion. If there be an infinite mass of fluid, then the stable existence of a vortex filament at any part necessitates motion throughout the whole, and there is, at the surface bounding the filament, no discontinuity of the kind apparently conceived by Mr. Preston.

Two vortices exercise very remarkable influences on one another, which are due to the irrotational motion of the parts of the fluid outside the vortices.

The existence of surfaces of finite slip in the hydrodynamics of an ideal perfect fluid is not precluded by any quality attributed to the fluid, but I do not think that the behaviour of vortices bounded by surfaces of slipping has been hitherto treated by any mathematician

It does not seem likely, however, that the investigation would lead to interesting physical results, because this kind of motion is essentially dynamically unstable.

Towards the end of the same article there occurs the following passage:—

"The old idea that a ship (or more correctly a totally immersed body, such as a fish) encountered a mysterious resistance in addition to the mere friction of the molecules on its sides, is now known to have been a pure delusion."

This statement appears to me either erroneous or very misleading. The resistances to the motion of a ship have been classified under three heads, viz., wave-making resistance, eddy-making resistance, and surface-friction.[1] For a totally-immersed body the wave-making resistance is non-existent, but Mr. Preston would appear only to take notice of the last of the three. Now whilst for a body with "fair lines," such as a fish, the eddy-making resistance may be small, yet if the lines are not fair it may be very large. Thus a fish leaves scarcely any wake, whilst an oar leaves a very great amount of disturbance.

Helmholtz, Kirchhoff,[2] and Lord Rayleigh[3] have made some interesting hydrodynamical investigations on the resistance suffered by a vane exposed to a current, on the hypothesis that in the wake of the vane there is dead water, separated from the moving water by surfaces of finite slip.

It has been already noticed that such a motion is dynamically unstable, but there is in many respects a remarkable accordance between the resistance as determined by this theory and that found experimentally,[4] so that it seems probable that the actual stable motion of flow, with eddies in the wake, does not differ very much from the theoretically unstable motion, with dead water in the wake. It will be noticed that this theory of resistance, which gives approximate results for bodies with very bad lines, such as flat vanes, actually entirely neglects surface-friction, to which Mr. Preston's statement would seem to refer the whole resistance.

Trinity College, Cambridge, May 27

The Inevitable Test for Aurora

IN reference to Prof. Piazzi Smyth's courteous criticism of our communication to the Royal Society on the aurora borealis, we regret that we are unable to say whether the critical citron line, to which he directs attention, was present or not in the spectra of the electric discharges in atmospheric air from which we deduced the probable heights of auroral displays. The experiments quoted were made without reference to the aurora, and this particular line was consequently not sought for, nor indeed have many measurements been made of the spectra of discharges in atmospheric air, on account of the time required and consequent great consumption of the life of the battery which such observations entail.

Cloud Classification

THERE is a proverbial objection to "looking a gift-horse in the mouth," and M. Poëy's Cloud Book is such a valuable addition to the scanty literature on the subject that it would be highly ungracious to make captious objections to his views. On the other hand, M. Poëy, when he differs from others, puts forward his views with such fairness and courtesy that I believe he would be the last man to deprecate full discussion.

Allow me then to put in a plea for certain old public servants, that they should neither be cashiered altogether, nor transported to strange regions, without full examination into their character and their merits.

First, then, for the *stratus*.

M. Poëy—happy man!—has carried on his observations under tropical skies and in the clear atmosphere of Paris. Had his lot been cast on the clays and gravels of the London basin I venture to think that he would have regarded the "stratus" with more respect, if with no increase of affection. He would have had frequent opportunities of observing it—at times resting entirely on the ground,[5] at others rising with a clearly defined lower and upper surface, a few feet (or even inches) from the earth, cutting the taller trees in a horizontal line, leaving their tops and bottoms free, and then being gradually dissipated, to be absorbed in the warmer air or to form *cumuli* at a higher elvation. He could hardly have failed to recognise it as a clear and distinct variety of *cloud*, the lowest in altitude of all the family, but none the less a member of it. If every cloud which has contact with our baser earth is to be cashiered on that account, what will become of M. Poëy's own cumulus on Plate XV.? Every mountaineer knows to his cost that if he happens to be on the mountain where such a cumulus is resting, he will be enveloped in a fog undistinguishable from what he finds on the Thames marshes.

Whether, on the other hand, it is desirable to use the term "stratus" for clouds in a totally different sky-region, which differ both in their origin and their nature from the true "stratus," is a question too long to be fully discussed here.

Next with regard to the *nimbus*.

M. Poëy's view appears to be that Howard's term applies to an isolated shower-cloud, and is unsuitable for a rain-cloud overspreading the sky. After careful reading of M. Poëy's remarks on the "pallium," and comparing them with Howard's description of the "nimbus," I entirely fail to see where lies sufficient difference to consign the "nimbus" to oblivion; and I can only imagine that M. Poëy has taken his idea[1] of what Howard meant almost entirely from the illustration, without noticing that Howard first describes the forming and behaviour of the cloud overhead in words curiously similar to those which Poëy himself uses for his "pallium," and then says, "But we see the nature of this process more perfectly in viewing a distant shower in profile." This clearly shows that the illustration was only chosen as the easiest form in which the cloud, *vel nubium congeries*, could be depicted, while the context guards completely against the name being limited to an isolated shower-cloud.

It would occupy to much space to place the descriptions of the two *savants* side by side, but I think that any one who will take the trouble to read the two together can hardly fail to see that Howard's "nimbus" fulfils all that Poëy describes as the rain-discharging cloud, including the upper "veil,"[2] or pallium of cirrus, the lower "sheet,"[3] or "pallium" of cumulus, and the "lower clouds arriving from the windward," which "move under this sheet and are successively lost in it" (Howard, p. 11; compare Poëy, Plate XII.). In fact, to use an expression frequently employed in the discussion of patents, you can take the description of the one inventor and "read it on to" the drawing of the other, or *vice versâ*.

M. Poëy's term "pallium" is certainly expressive, and will probably make itself a home in cloud terminology; but it appears after all only to mean that a certain modification overspreads the whole or a large part of the sky (compare Howard, p. 11), and does not by any means cover that combination of clouds which produces rain ("nimbus.")

I must leave it to a future time or to other pens to discuss the merits of the "cumulo-stratus," and pass on to examine shortly M. Poëy's views about the "cumulus." The Rev. W. C. Ley, in his review of M. Poëy's work, in your pages, has already pointed out the illogical nature of the author's repeated remark that the "cumulus" only exists in the horizon, forgetting that a cloud which is on the horizon of one place must be in the zenith of another. Now I venture to suggest that this curiously-distorted mental view affects M. Poëy's classification far more than appears at first sight. If clouds are considered not objectively according to their whole form and structure, but subjectively as they present themselves to an individual observer, we naturally need new modifications as the clouds are viewed in different positions. Are not many of the clouds which M. Poëy calls "fracto-cumulus" simply "cumuli" viewed from beneath? Just as (to borrow a simile from Mr. Ley) an elm-tree seen from beneath presents a spreading, ragged edge, and shows the blue sky through its interstices, whereas on the horizon it appears compact, rounded, and sharply defined.

May I add a practical suggestion as to the popular terms proposed by M. Poëy on p. 39? These terms are put forward as an alternative to the scientific Latin names, for the use of *non-scientific observers*, who may be of great service in collecting information at out-stations where no trained meteorologist is at hand. It is therefore all-important that they should be as short,

plain, and simple as possible, conforming as nearly as may be to the popular terms in use, and above all that there should be nothing to mislead an ignorant person. Now I would ask what idea is conveyed to an ordinary unscientific mind by the term "snow-sheet"? The name is perfectly correct if read in the light of M. Poëy's explanation; but to an average lighthouse-keeper or coastguard it would certainly convey the idea of a so-called "pallio cumulus," *ready to discharge snow*, and would be used accordingly.

"Wind cloud" appears also distinctly misleading. To most minds it would, I believe, imply a cirrus or cirro-cumulus, as being the harbinger of wind. We have two excellent names in common use—"scud" and "rack,"—either of which would serve.

"Stratified cloud" is a very vague term, applicable to many varieties besides "cirro-stratus."[1]

Objections might also fairly be raised against "Belt cloud," as compared with the familiar "Noah's ark" which Poëy himself quotes elsewhere, and to the "Globular tempestuous cloud," as a very cumbrous term, although a correct one.

It is to be hoped that all these details will be fully discussed before M. Poëy's suggestions are either admitted into general use, or, on the other hand, too readily rejected. E. H.

"Chipped Arrow heads"

IN a number of NATURE (vol. xx. p. 483) which only lately reached us here I read an interesting account of Mr. Cushing's researches into the manufacture of flint weapons as practised by aboriginal tribes; and as I have had many opportunities of observing the method by which the Fuegians of Magellan's Straits fashion their glass arrow-heads, a few words on the matter may not be without interest to some of your readers.

One of the indications of the increase of traffic through these Straits which has of late years taken place is that empty bottles are now to be found about the shores of those anchorages which are used by passing vessels as stopping-places for the night; and bottle-glass is consequently the material used by the Fuegians of the present day, to the exclusion of obsidian, quartz, or flint. The following is the process:—A fragment somewhat approaching to the shape of the intended arrow-head is grasped firmly in the left hand, while in the right hand is held an old iron nail stuck into a short wooden handle. The fingers of the closed right hand are turned upwards, and the point of the nail is directed towards the operator's breast. He then presses with great force the blunt point of the nail obliquely against the edge of the piece of glass, when a thin scale flies off towards him. One side of the edge having been bevelled in this way, the glass is turned round, and the opposite edge flaked off in a similar manner. Working the edges alternately in this way, the glass is readily brought to the required shape. The fashioning of the point is the most difficult part of the process, the formation of the barbs being easily effected.

I have seen a native thus make a large arrow-head out of a piece of broken pickle bottle in about half an hour. The glass is never struck, but is fashioned entirely by pressure. After a little practice I succeeded in making fair imitations.

I find, moreover, that the iron tool above mentioned can be dispensed with, and that the flaking may be effected by pressing with an angular flint or with a piece of *bone*, which were probably the methods used by the Fuegians before they possessed any iron implements. R. W. COPPINGER

H.M. Surveying Ship *Alert*, Swallow Bay, Straits of Magellan, March 21

Cup and Ring Stones

IN reply to Mr. Middleton's letter I beg to say that the Ilkley cup and ring stones have been carefully described and illustrated in a paper read by me before the Brit. Archæolog. Assoc. (see *Journal* B. A. A. for 1879, p. 93).

Further information will be found in Sir Jas. Simpson's work on the subject, which forms the appendix to vol. vi. of the *Proc.* Soc. Ant. Scot., and in Prof. Boyd Dawkins' "Early Man," p. 338.

In a large number of instances cup and ring marks have been found on the stones of cists, stone circles, and menhirs. It would therefore appear that they are connected with sepulchral rites. Cup marks are found in Scotland, Ireland, Wales, Northumberland, Yorkshire, Cumberland, Lancashire, Switzerland, Sweden, and India (see Rivett Carnac's papers in *Journal* of Asiatic Society of Bengal, 1878–9). I should be glad of evidence of their existence in Derbyshire and elsewhere in the South of England. J. ROMILLY ALLEN

23, Maitland Street, Edinburgh

[1] I am not aware whether *Geschichtete Wolken* is an accepted term in Germany. In the Bernese Oberland a very expressive name is used, *Geströifte Wolken*, only too well known to mountaineers.

Songs of Birds

CAN any musical reader of NATURE transcribe for me the notes of the king lorry (*Aprosinectus scapulatus*)? May not the *major* and *minor* keys of the cuckoos noticed by John Birmingham be sexual characteristics? The males are believed to exceed the females in number in the proportion of four or five to one, and, if this be so, the male note must be heard more often than the female. The "jerkiness of style" in the *major* cuckoo, as described, suggests that the performer is a female. A. N.

C. W. HARDING.—The teeth belong to a young horse—not yet "in mark" (*Equus caballus*). Their geological horizon appears uncertain, and they are as likely to be historic or prehistoric as pleistocene.

COMPARATIVE ANATOMY OF MAN[1]

III.

Modifications of the Negro type.—At several parts of the equatorial region of Africa, from the Gulf of Guinea to the White Nile, indications have been met with of a small race of negroes, sometimes so small that the name of pygmy may truly be applied to them, differing from the ordinary negro in the short rounded form of the head. These bear some resemblance to the diminutive members of the oceanic black races who inhabit some parts of the East Indian Archipelago, especially the Andaman Islands, and to whom the name *Negrito* is now generally applied, and Dr. Hamy, who has collected together all the evidence at present accessible as to their existence, has proposed to distinguish them by the term *Negrillo*. The Akkas of Schweinfurth appear to belong to this race. In many districts they are more or less mixed with the ordinary negroes, and their physical characters are therefore obscured, but some skulls from the West Coast of Africa in the collection of Dr. Barnard Davis bear a striking resemblance to those of the Andamanese, and have a cephalic index of 80 or upwards.

The greater part of Africa, between the equator and the most southern parts, where the Hottentots and Bushmen dwell, is inhabited by negroes, who for linguistic reasons are grouped together, and separated from the more northern tribes, and are now generally known to ethnologists by the name of *Bantu*. Their range seems to have extended southwards in comparatively recent times, encroaching upon that of the original inhabitants. They are a pastoral people, warlike, energetic, and intelligent, owning large herds of cattle, and living in villages composed of a number of beehive-like huts. The southern Bantu, who at present are the best known, from their vicinity to the British and Dutch settlements of South Africa, are divided by Fritsch into 1. The Ama-Xosa, who inhabit at present the south-east portions of the Bantu territory, adjoining the sea, between the Cape Colony and Natal. To these the name *Kafir*, derived from an Arabic word applied to them as unbelievers or heathens, is commonly given, but the name is sometimes used in a wider sense for the Bantu negroes generally. The Ama-Xosa include the well-known tribes of Gaikas and Galeikas, with whom we were at war in 1877. 2. The Ama-Zulu,

[1] Abstract Report of Prof. Flower's lectures at the Royal College of Surgeons, March 1 to March 19, on the Comparative Anatomy of Man. Continued from p. 80.

situated to the north of these, in Natal and Zululand. 3. The Bechuanas, occupying the central or inland country; and 4. The Ova-hereros, or Damaras, of the western coast-lands. Each of these divisions is composed of numerous small tribes, frequently at war with each other, and constantly changing in relative importance and even locality. The growth of the Zulu nation is a striking example of the mutable character of native African political combinations. At the commencement of the present century they were an extremely insignificant tribe, but by the military and political genius of their chief, Chaka, who conquered and absorbed all the neighbouring tribes, a powerful kingdom was formed, which was consolidated by his successors, Dingaan, Panda, and Ketchwhyo, under whom, however, it has been destroyed by the superiority of European weapons and organisation, at what cost we know too well. Five crania of Zulus who were killed in the fatal battle of Isandthlwana, on January 22 of last year, have already reached the museum, through the kindness of Mr. Fynn, a magistrate in Natal, Col. Mitchell, the Colonial Secretary, and Dr. R. J. Mann, and their uniformity of characters is such that they probably are very fair average specimens of the race. They are the skulls of large, powerful men in the prime of life. The capacity of their cranial cavity is remarkable, far above that of the ordinary negro, even above that of the lower class of Englishmen, the average of the five being 1,580 cubic centimetres. One measures as much as 1,745. Their average latitudinal index is 75·1, their altitudinal index 76·6. Their orbits are remarkably small and low; index 81·7. The form of the nasal bones and nasal index (60·7) is characteristically negroid, but they differ from ordinary negroes in two important points. They are not truly prognathous, but mesognathous, the alveolar index (100·4) being intermediate between that of the negro and the European, and their teeth are small, the index being only 40·7. The crania of other Zulu and Kafir tribes previously examined give similar results, especially a larger cranial capacity and a less degree of prognathism than is found in the equatorial negro.

Another great division of South African people comprises those popularly known as Hottentots and Bushmen, or in their own language Koi-Koin. They formerly inhabited a much larger district than at present; but, encroached upon by the Bantu from the north and by the Dutch and English from the south, they are greatly reduced in numbers, and indeed threatened with speedy extinction. The Hottentots are at present divided into three principal groups—the Namaquas, Korannas, and the Griquas. The latter especially are much mixed up with other races, and, under the influence of a civilisation which has done little to improve their moral condition, they have lost most of their distinctive peculiarities. The pure-bred Hottentot is of moderate stature, has a yellowish-brown complexion, very frizzly hair, which, being less abundant than that of the ordinary negro, has the appearance of growing in separate tufts. The forehead and chin are narrow and the cheek-bones wide, giving a lozenge-shaped visage. The nose is very flat and the lips prominent. The women are often remarkable for immense accumulation of fat upon the nates, called *steatopygy*, and also of great elongation of the nymphæ and of the *preputium clitoridis*. In these anatomical peculiarities, and in almost everything else except size, the Bushmen agree with the Hottentots. In fact they appear to be a stunted, outcast branch of the same race living the life of the most degraded of savages among the rocky caves and mountains of the lands where the comparatively civilised and pastoral Hottentots dwelt in the plains. Their usual appellation is derived from the Dutch Bosjesman, or "man of the woods," and they have been regarded both by Kafirs and Boers as something only half human, and have been treated accordingly, and nearly exterminated. Notwithstanding their generally low condition of culture, they show remarkable pictorial power, drawing animals especially with life-like accuracy. The osteological characters of the Bushmen are tolerably well illustrated in the museum both by skeletons and crania. Their average height would appear to be from 4 feet 6 to 4 feet 8 inches, and there is very little, if any, difference between the men and women in this respect. The form of the skull is extremely characteristic, and could scarcely be mistaken for that of any other race. It has generally a very feminine, almost infantile appearance; though the capacity of the cranial cavity is not the smallest, exceeding that of the Andamanese and the Veddahs of Ceylon. In general form the cranium is rather oblong than oval, having straight sides, a flat top, and especially a vertical forehead, which rises straight up from the root of the nose. The lower occipital region is greatly developed, in marked contrast to that of the Andaman islanders. They are moderately dolichocephalic or mesaticephalic, the average of ten specimens being 75·4. The height is in all considerably less than the breadth, the average index being 71·1, so that they are decidedly low skulls. The zygomata are little developed, the malars project forwards about as much as in the Mongolian races, giving a nasi-malar angle of 140°. The glabella and supra-orbital ridges are little developed except in the oldest males. The orbits are elongated and low (average index 81·4), the space between the orbits very wide and flat, there being no depression at the root of the nose. A large portion of the ascending process of the maxilla is visible on each side of the nasals. The nasal bones are extremely small and flat, and the aperture wide; the average nasal index being 60·8, so that they are the most platyrhine of all races. On the other hand they are rarely prognathous. In this, and some other characters, there is much that recalls the infantine condition of the true negro.

Inhabitants of North Africa.—The whole of the various populations inhabiting the portion of Africa north of the Sahara Desert, from the Atlantic coasts as far south as the River Senegal on the west to the Red Sea on the east, belong to a completely different type of mankind from that which we have been last considering, and, as before mentioned, the boundaries between the two types coincide remarkably with those of zoological regions, as indicated by distinct characters of the fauna. As must naturally have happened during the vast length of time during which the people of Northern Africa and the negroes have occupied contiguous regions since the drying up of the Sahara Sea, with absolutely no physical barrier between them, considerable intermixture has taken place along the frontier line, and even for some distance into the territories of each at certain points. In the east, especially, the superior northern race has encroached far southwards, and the practice, which has existed from the most ancient times down to our own, of importing the negroes into the northern country as slaves and soldiers, has given rise to a considerable modification of the type in certain districts.

Besides the negro element which has thus partially and locally modified the characters of the inhabitants of Northern Africa, at least two other adventitious elements, although with differences small compared with those last named, appear to have come into the district and assisted to diversify the physical type. The evidence on which the first of these rests is rather shadowy; but to account for the considerable number of individuals, especially in Marocco, who depart at least in colour from the prevailing North African type, and have fair complexions, eyes, and hair, an immigration of a northern race is supposed; and as all such immigrations within the strictly historic period, such as that of the Vandals (A.D. 500) have been on too small a scale or too temporary to effect such a permanent change in a considerable portion of the

population, and as there is evidence from Egyptian monuments of fair people (the Tamahou) inhabiting North Africa, to the west of Egypt, at least 1500 years B.C., this race has been associated with the builders of the megalithic monuments found scattered over the west of Europe and the north-west of Africa, who are supposed to have invaded Africa by way of Spain and Tangiers. The invasion of the country by Semitic races from the East, the Phœnicians and Carthaginians, and more recently the Arabs, who overspread North Africa by way of the Isthmus of Suez in the seventh and tenth centuries, and impressed the Mohammedan religion upon all these regions, rests upon surer historical evidence. The basis of the population of Marocco, Algiers, and Tunis are the Berbers, descendants of the Libyans or *Lebou* of the ancient Egyptians. An important section of them are the Kabyles of the French. They are mostly a settled and pastoral people. The Moors are mixed descendants of Arabs and Berbers, residing in towns. The Bedouins are the Arabs who still lead a nomadic life in the desert. There is much in common in the physical characters of all these people, and indeed with those of the South of Europe and South-West of Asia. They belong mainly to the group called *Melanochroi* by Prof. Huxley.

The Berber type, which perhaps forms the basis of the population of North Africa, is thus described by Topinard, by whom it has been carefully studied. The height is slightly above the mean, 1·68m. *i.e.*, 5 feet 6·1 inches. The skin, white in infancy, quickly becomes brown by contact with the air; hair black, straight, and abundant; eyes dark brown; skull dolichocephalic (index 74·4), leptorhine (44·3), and moderately orthognathous. The face is less elongated and of a less regular oval contour than in the Arab. The straight forehead presents at the base a transverse depression; the superciliary crests are well developed; the nose is sunken at the base, often arched without being aquiline. The moral and social qualities of the Berbers are contrasted with those of the Arabs, considerably to the disadvantage of the latter.

The enterprising and commercial spirit of the Arabs has led to their extension over a very considerable part of Africa, along the north as far as Marocco, and down the east coast beyond Zanzibar, and once, in association with Berbers, and under the name of Moors, they effected a lodgment for a considerable period in Spain and the south of France. Physically they are a fine race. Their skull, seen from above, forms a perfectly regular oval. Their face, long and thin, forms another oval, with a not less regular contour, pointed below. Their colour is perfectly white until subjected to the action of the air, when it bronzes with facility. The hair and beard are smooth, and black as jet, the limits of their implantation are clearly marked: eyes black, the palpebral openings elongated, almond-shaped, and bordered with long black eyelashes; forehead not much elevated. The curve of the nose and retreating chin give to the profile a form rather rounded than straight. The superciliary arches and glabella little developed; the root of the nose is little hollowed, so that the forehead and the dorsum of the nose are almost in a straight line. The nose is aquiline, and its point detaches itself from the alæ and descends downwards, recurved like the beak of an eagle. The cheek-bones do not project; the mouth is small, the teeth white and vertical, the ears well made and rather small, and close to the head. The skull is subdolichocephalic (index 74·0), and the nose leptorhine, 45·5.

A branch of the North African people which has received much attention from anthropologists is that called Guanche, which formerly inhabited the Canary Islands, and which previous to the discovery and conquest of the islands by the Spaniards in the fourteenth century had long been isolated from all other people, and had attained to a peculiar civilisation of its own, preserving somewhat of the purity of type generally found under such circumstances. The custom of embalming their dead in a mummified condition in rock sepulchres has permitted us to become acquainted with their physical characters. They were of small stature, and rather resembled the Berbers of the adjoining coast than any of the negro races. Their skull was of the mesaticephalic form, having an average cephalic index of 76·5, and was considerably lower than it was broad. The face was not prognathous, the nose was leptorhine, and at least those inhabiting the island of Teneriffe, who are best known to us, are remarkable for the low and elongated orbits, having, according to Broca, the lowest orbital index (77) of any race. In this respect and some others they resemble the ancient skulls of the reindeer period found in the cave of Cro-Magnon in the South of France, and it has been thought that they may be related to that race. It should be mentioned, however, that the Guanche skulls from Teneriffe in the collection of Dr. Barnard Davis do not altogether bear out this view, as they have a considerably higher orbital index than those measured at Paris.

Of all the people of North Africa the Egyptians are undoubtedly the most interesting. "When history begins to dawn, the first object the light strikes upon, and which for a long time alone rears its form above the general gloom, is the civilisation of ancient Egypt. On inquiry we find this thoroughly-organised civilisation, fully supplied with all the necessaries and many of the embellishments of life, and which is alone visible in the dawning light, must have existed through ages long prior to the dawn. It recedes into the unfathomable depth of time far beyond the monuments and traditions." The valley of the Nile has been for thousands of years the scene of many events which have affected the ethnological characters of its population. Invasions and conquests more or less complete from the east, the north, the west, and the south; importation to its interior from all the regions around of prisoners and slaves in enormous numbers, many of whom have become permanent settlers and integral parts of the population: yet through all the lapse of years since the period from which the first evidence of the condition of man in that region has come down to us to the present day the mass of the population, through all the political vicissitudes which they have undergone, have presented the same general physical type. Notwithstanding the mixture of Semitic or Syro-Arabian nations, as in the Hyksos, who ruled in the Delta for nearly 500 years, and the Arabs of later times, the less important Phœnician, Jewish, and Greek immigration in the north, that of the Persians from the east, and Lybians from the west, and the Ethiopians from the south, the Copts and Fellahs of modern Egypt are the little changed lineal descendants of the subjects of the Pharaohs of the early empire. The physical characters of these are preserved to us fortunately by artistic representations, graphic and sculptural, and the still more trustworthy evidence of mummified bodies. Although there are considerable signs, as might be expected, of admixture with other races here and there, the general uniformity is striking, especially as it extends through so long a period of time. If variations appear at particular epochs the original type constantly reasserts itself, almost, if not quite, in its primitive purity.

In size the ancient Egyptians were not large, and rather delicately built; their hair was long, soft, straight, or wavy, and black; their cranium oval in form, and the average cephalic index is on the borders between mesaticephaly and dolichocephaly, and tolerably uniform in different series, collected and measured by different observers. Thus Morton gives the average of 43 specimens in American museums as nearly 75; Broca that of 81 crania at Paris as 75·58; while the average of 33 in the College museum is 75·4. Of the latter but one is as high as 80·7, and one as low as 69·6. Of the others, 20 are

above 75·0, or belonging to the mesaticephalic class, and 11 below 75·0, or dolichocephalic. The average altitudinal index is below that of the latitudinal, viz., 73·1. The average cranial capacity of the males is 1,454 cubic centimetres. They are almost as orthognathous as Europeans, and have teeth of the same comparatively small size, the dental index being in 7 male skulls 40·8, and in 8 females 41·2. The nasal index of 81 measured by Broca was 47·88, and this was found to be tolerably constant in mummies of different historical periods. The average nasal index of 25 in the College collection is rather higher, viz., 48·7. The orbital index of the same crania is 86·2. Of modern Copts unfortunately but few crania have been hitherto available for examination; but Broca gives the latitudinal index of 12 at 76·39, and the nasal index at 47·15.

The cranial and other characters of the Egyptians correspond in the main with those of the Berbers and other inhabitants of North Africa, and they must be placed in the same general category in any classification of the human race founded on anatomical characters. They have no affinities with the negroes, except such as may easily be accounted for by the occasional admixture of negro blood. Indeed it is almost remarkable that there are not more signs of this having taken place. Some authors have supposed a Turanian origin for the Egyptians, but if this term is to be taken in any sense as equivalent to Mongolians, there is absolutely no support for it in their osteological characters; all the characteristics of the Mongolian races are entirely absent in the Egyptian skull. Still less can any resemblance be seen to the Australian, whose skull, compared with that of an Egyptian, presents almost as great a contrast as can be found within the limits of variation of the human cranium. The angular form, limited capacity, wide zygomata, projecting supraorbital ridges, short flattened nasals, wide nasal aperture with rounded inferior border, great alveolar prognathism, retreating chin, and immense teeth, characteristic of the Australian, are all wanting in the Egyptian. In fact the Egyptian belongs by all his anatomical characters to the type called by Blumenbach Caucasian. The much vexed questions, Who were the Egyptians? and Where did they come from? receive no answer from anatomical investigations, beyond the very simple one that they are one of several modifications of the great group of races which inhabit all the lands surrounding the Mediterranean Sea; that they here lived in their own land far beyond all periods of time measured by historical events, and that in all probability it was there that they gradually developed that marvellous civilisation which has exercised such a powerful influence over the arts, the sciences, and the religion of the whole of the Western world.

THE UNITED STATES WEATHER MAPS, SEPTEMBER, 1877

IN Canada and the United States during September, 1877, atmospheric pressure was everywhere above the normal except over a small triangular patch bounded by the Gulf of Fundy, Chesapeake Bay, and the entrance to Lake Superior. The deficiency was greatest in the North-Western States from Leavenworth to Lake Winnipeg, where it amounted to nearly the tenth of an inch, and on the coasts of the Gulf of Mexico, the deficiency at Mobile being 0·074 inch. Pressure was also under the normal over Greenland, the Atlantic, the Spanish Peninsula, Italy, nearly all Austria and Prussia, the whole of Russia and Siberia, except a patch stretching in a N.N.E. and S.S.W. direction about Lake Baikal. The centres of greatest depression were in the Atlantic between Greenland and the Azores, over a rather broad region extending eastwards from Moscow to the Obi, and from Pekin northwards to Nertschinsk, the greatest depressions below the normals of these regions for September being respectively 0·112 inch, 0·130 inch, and 0·051 inch.

Pressures were above the normal over the whole of North-Western Europe, including Iceland, Sweden, Norway, Denmark, the Netherlands, France, and Germany as far as Pressburg, the greatest excess, 0·303 inch, occurring in the extreme north-west of the British Islands. But the most extensive region of unusually high pressure embraced the whole of Southern Asia, including Japan, China, except the extreme north, India, Syria, and also Egypt; and the whole of Australia, Tasmania, and New Zealand was also above the normal, and very considerably so, the excess at Deviliquin, on the Murray River, reaching 0·265 inch.

The most remarkable disturbance in the temperature arising out of this abnormal distribution of pressure and the winds necessarily resulting therefrom, occurred over the whole of Europe, except Italy and the Spanish Peninsula. If the Weather Map be examined, it will be seen that from the west of the British Islands pressures steadily diminished on proceeding eastward over Europe, and along with this diminution of pressure pretty strong northerly winds prevailed, except in the two peninsulas already referred to, where winds were southerly and the temperatures consequently above the normal. Under the influence of these northerly winds the temperature of Europe from the North Cape southwards fell greatly below the average, a deficiency of 5°·0 or upwards being experienced at the North Cape, Christiania, Memel, Gulynki, Warsaw, and Prague. In Siberia, to the east of this cold region, southerly winds prevailed and high temperatures consequently ruled, the excess above the normal temperature being 6°·3 at Taschkent, 4°·0 at Semipalatinsk, and 2°·5 at Jenisseisk and Irkutsk. Southerly winds also prevailed over Iceland and Greenland, raising the temperature above the normal, the excess on the west of Greenland being about 4°·0, and in the north-west of Iceland 5°·0. The Weather Map shows strong southerly winds also over Canada and the northern half of the United States, where consequently the temperature was high for the season, the excess being from 2°·0 to 3°·0, rising even at some places to nearly 4°·0. Further south the excess was much less; and in some cases there was even a deficiency, as about Cape Hatteras, where northerly winds will be seen from the Map to have swept over that coast, and the temperature fell a degree and a half below the average; and along the upper reaches of the Arkansas and Red rivers, or to westward of the region of lowest pressure, where, winds being north-westerly, the temperature fell nearly a degree below the normal.

In India, pressure was unusually and continuously high from the beginning of the year, except in August, when it fell below the average over the region of the Lower Ganges and Assam. In September, however, pressure again became unusually high over all India, the excess being greatest along the northern coasts of the Bay of Bengal and the central districts from Visagapatam to Ajmere. In Assam the excess was considerable and the rainfall exceeded the average, whereas in Orissa, Western Bengal, and Berhar the rainfall was scanty. The excess above the normal pressure was also considerably less over Southern India and Ceylon than it was to northward; and with this distribution of the pressure occurred the memorable feature of the meteorology of India for the month, viz., an unusual strength of the south-west monsoon over the west of India from Goa southward, accompanied with an abnormally heavy rainfall on that coast, which extended eastward over the Deccan and the greater part of the Madras Presidency, and thus terminated the disastrous famine which had wasted Mysore and a large portion of the Madras Presidency during the previous two years.

CONTRIBUTIONS TO MOLECULAR PHYSICS IN HIGH VACUA[1]

THIS paper is a continuation of the Bakerian Lecture "On the Illumination of Lines of Molecular Pressure and the Trajectory of Molecules," read before the Royal Society, December 5, 1878. Phenomena there briefly referred to have since been more fully examined; new facts have been observed, and their theoretical bearings discussed; and numerous experiments suggested by Prof. Stokes and others have been tried, with the result of acquiring much information which cannot fail to be of value in assisting to evolve a theory capable of embracing all the phenomena under discussion.

Experiments previously described have shown that the molecular stream hypothesis is the correct one. According to this, the molecules of the residual gas, coming in contact with the negative pole, acquire a negative charge, and immediately fly off by reason of the mutual repulsion exerted by similarly electrified bodies. Were the individual molecules solely acted on by the initial impulse from the negative pole, they would take a direction accurately normal to the surface repelling them, and would start with their full velocity. But the molecules, being all negatively electrified, exert mutual repulsion, and therefore diverge laterally. The negative pole, likewise, not only gives an initial impulse to the molecules, but it also continues to act on them by repulsion, the result being that the molecules move with an accelerating velocity the further they get from the pole. The lateral divergence of the molecules, owing to their negative electricity, will naturally increase with the amount of charge they carry; the greater the number of collisions the more the molecules lose negative charge, and the less divergent the stream becomes. This hypothesis is borne out by facts. When the vacuum is just good enough to allow the shadow to be seen, it is very faint (owing to few molecular rays), but is quite sharp (owing to the divergence of the molecules laterally). The variation in mutual repulsion is shown by the fact that the focus projected from a concave pole falls beyond the centre of curvature, and varies in position with the exhaustion, being longer at high than at low exhaustions.

Assuming that the phosphorescence is due, either directly or indirectly, to the impact of the molecules on the phosphorescent surface, it is reasonable to suppose that a certain velocity is required to produce the effect. Within the dark space, at a moderate exhaustion, the velocity does not accumulate to a sufficient extent to produce phosphorescence; but at higher exhaustions the mean free path is long enough to allow the molecules to get up speed sufficient to cause phosphorescence. At a very high exhaustion the phosphorescence takes place nearer the negative pole than at lower exhaustions; this I consider results from the initial velocity of the molecules being sufficient to produce phosphorescence, their greater speed being due to the fewer collisions near the negative pole.

The luminous boundary to the dark space round the negative pole is probably due to the impact of molecule against molecule, producing phosphorescence of the gas in the same way as the impact of molecules against German glass produces phosphorescence of the glass.

The following experiments were commenced at the suggestion of Prof. Maxwell:—

A tube was made as shown in Fig. 1. The terminal *a*

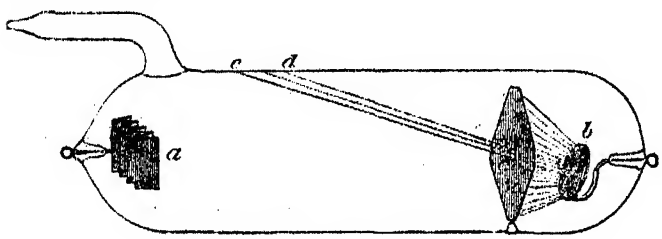

FIG. 1.

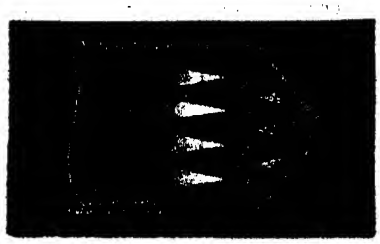

FIG. 2.

is a rectangular plate of aluminium, folded as shown in section Fig. 2; the other terminal *b* is a flat disk of aluminium set obliquely to the axis of the tube. In front of the pole *b* is fixed a screen of mica, with a small hole in it, as shown at *c*; this hole is not in the axis of the tube, but a little to one side of it, so that rays starting normally from the centre of the pole *b* may pass through it and strike the glass at *d*, whilst at the same time rays passing direct between the poles *a* and *b* can also pass through the hole.

The questions which this apparatus was to answer are: (1) Will there be molecular projections from the negative pole, *a*, in two series of plane strata normal to the sides of the individual furrows, or will the projection be perpendicular to the electrode as a whole, *i.e.*, along the axis of the tube? and (2), Will the molecular rays from the pole *b*, when it is made negative, issue through the aperture of the screen, along the axis of the tube, *i.e.*, direct to the positive pole, or will they leave the pole normal to its surface and strike the glass as shown at *d*?

The tube was exhausted and connected with an induction coil; the following results were obtained:—At a moderate exhaustion, the corrugated pole being made negative, the dark space entirely surrounds it, slight indentations being visible opposite each hollow, where there also is a linear concentration of blue light. The appearance is in section as shown in Fig. 2. At higher exhaustions the luminous margin disappears and the rays which previously formed the blue foci are now projected on the inner surface of the tube, where they make themselves evident in green phosphorescent light as portions of ellipses formed by the intersection of the several sheets of molecular rays with the cylindrical tube. Fig. 3 shows this appearance.

FIG. 3.

When the other pole was made negative, and the

[1] "Contributions to Molecular Physics in High Vacua. Magnetic Deflection of Molecular Trajectory; Laws of Magnetic Rotation in High and Low Vacua; Phosphorogenic Properties of Molecular Discharge." By William Crookes, F.R.S. (Extracts from a paper in the *Philosophical Transactions* of the Royal Society, Part 2, 1879.)

exhaustion was such that the dark space extended about 8 millims. from the pole, the first appearance noticed was that of a ray of dark blue light issuing through the hole in the mica screen, and shooting upwards towards the side of the tube, but not reaching it. Fig. 4 shows the

FIG. 4.

dark space round the pole, and the ray of blue light. On increasing the exhaustion this blue line of light, and the luminous boundary to the dark space, disappeared, and presently a green oval spot appeared on the side of the tube, exactly on the place previously marked where the rays issuing normal from the surface of the pole should fall.

It happened that this oval spot fell on a portion of the tube where one of the elliptical projections from the opposite (corrugated) pole also fell when that was made negative. Thus by reversing the commutator I could get a narrow band of green phosphorescent light from one pole, or a wider oval of green light from the other pole, to fall alternately on the same portion of the glass. Fig. 5 shows these effects, which, however, did not occur together as represented in the figure, but alternately.

The narrow band shone very brightly with green phosphorescence, but on reversing the commutator and obtaining the oval spot, this was seen to be cut across the middle by a darker band where the phosphorescence was much less intense. The light of the band was always more intense than that from the spot; the impacts from the one being more concentrated than from the other, owing to the shape and position of the poles; moreover the experiments had been first tried with the corrugated pole negative. The glass along the band gradually becomes deadened by repeated impacts, and will not readily phosphoresce in reply to the weaker blows from the flat plate, although it still responds to the more energetic bombardment from the corrugated pole. This phenomenon almost disappears at very high exhaustions, or if the tube is allowed to rest for some time. The tired glass then recovers its phosphorescent power to some extent, but not completely.

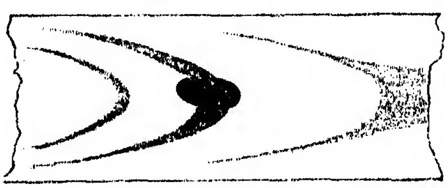

FIG. 5.

To obtain this action in a more striking manner, a tube was made having a metal cross on a hinge opposite the negative pole. The sharp image of the cross was projected on the phosphorescent end of the bulb, where it appeared black on a green ground. After the coil had been playing for some time a sudden blow caused the cross to fall down, when immediately there appeared on the glass a bright green cross on a darker background. The part of the glass formerly occupied by the shadow, having been protected from bombardment, now shone out with full intensity, whilst the adjacent parts of the glass had lost some of their sensitiveness, owing to previous bombardment.

This effect of deadening produced on glass by long-continued phosphorescence was shown in a very striking manner at a lecture delivered at the Royal Institution on April 4, 1879, when the image of a cross was stencilled on the end of a large pear-shaped bulb.

I subsequently experimented further with this bulb, and found that the image of the cross remained firmly stencilled on the glass. The bulb was then opened and the wide end heated in the blowpipe flame till it was quite soft and melted out of shape. It was then blown out again into its original shape, and re-exhausted; on connecting it with the induction coil, the metal cross being down out of the line of discharge, the original ghost of the cross was seen to be still there, showing that the deadening of the phosphorescing powers the glass produced by the first experiment at the Royal Institution had survived the melting-up and re-blowing out of the bulb.

When experimenting with this apparatus a shifting of the line of molecular discharge was noticed when the current was first turned on. The flat pole *b* (Fig. 6) being

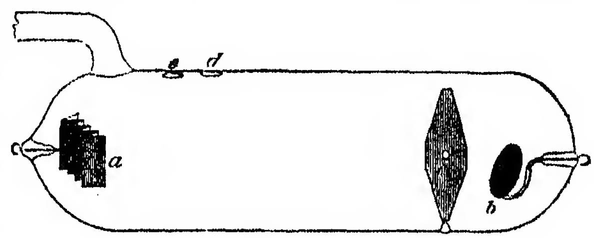

FIG. 6.

negative and the line *cd* being normal to its surface, the spot of light falls accurately on *d*, when the exhaustion is sufficiently good to give a sharp oval image of the hole *c*. But at higher exhaustions, when the outline of the image of *c* becomes irregular and continually changing, the patch of light at the moment of making contact is sometimes seen at *e*, and then almost instantly travels from *e* to *d*, where it remains as long as the current passes. The passage of the spot from *e* to *d* is very rapid, and requires close attention to observe it. If the coil is now stopped for a longer or shorter time, and contact is again made *the same way as before* (*b* being negative), the spot does not now start from position *e*, but falls on *d*, in the first instance. This can be repeated any number of times.

If now the pole *b* be made positive even for the shortest possible interval, and it then be made negative, the original phenomenon occurs, and the spot of light starts from *e* and rapidly travels to *d*. After this it again falls on *d*, *ab initio*, each time contact is made, so long as *b* is kept the negative pole. There seems no limit to the number of times these experiments can be repeated. The explanation of this result appears to depend on a temporary change in the condition of the wall of the glass tube when positively electrified molecules beat against it, a change which is undone by subsequent impact from negative molecules. This phenomenon is closely connected with some shadow and penumbra experiments described further on, and as the same explanation will apply to both I will defer any theoretical remarks for the present.

A suggestion was made by Prof. Maxwell that I should introduce a third, idle, electrode in a tube between the positive and negative electrodes so that the molecular stream might beat upon it, so as to see if the molecules gave up any electrical charge when impinging on an obstacle. A tube was therefore made as shown in Fig. 7; *a* and *b* are the ordinary terminals; *c* and *d* are large aluminium disks nearly the diameter of the tube, con-

nected with outer terminals. The poles *a* and *b* were connected with the induction coil, an earth wire was brought near the idle pole *c*, and a gold leaf electroscope was brought near *d*.

On passing the current at inferior exhaustions, when the dark space is about 8 millims. from the negative pole,

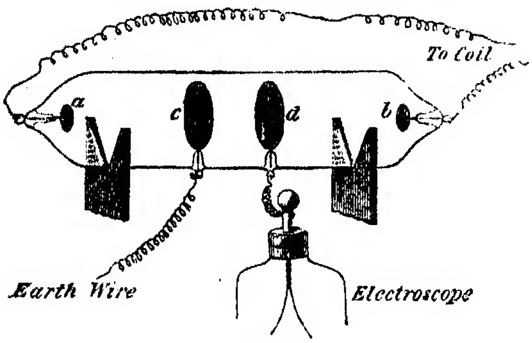

FIG. 7.

no movement of the gold leaves takes place whether *a* or *b* is negative, and whether *c* is connected with earth or is insulated.

At a good exhaustion, when the green phosphorescence of the glass is strong, the gold leaves are only slightly affected whichever way the current passes.

On increasing the exhaustion to a very high point, so that the green phosphorescence gets weaker and the spark has a difficulty in passing, the gold leaves are violently affected. When the pole *a* is negative and *b* positive, the leaves diverge to their fullest extent. On examining their potential it is found to be positive. The coil was stopped and the gold leaves remained open. A touch with the finger caused them to collapse. They then gradually opened again, but not to the original extent. The finger again discharged them, when they reopened slightly a third time. Experiment showed that the electrical excitement took many minutes to recover equilibrium. A Leyden jar put to the idle pole *d* was charged positively.

The earth wire and electroscope remaining, as shown in the figure, the direction of current was reversed so as to make *a* positive and *b* negative. The gold leaves were now less strongly affected; they opened a little, and remained quivering, as if under the influence of rapidly-alternating currents.

The wires were rearranged as shown in Fig. 8, *b* and *d*

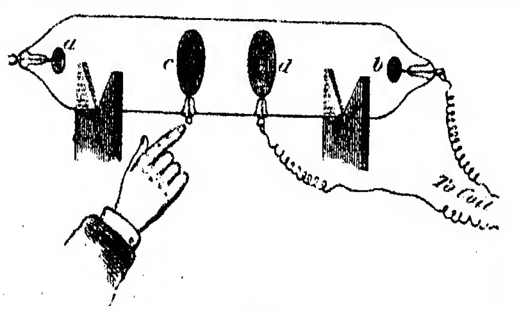

FIG. 8.

being connected with the coil. When *d* was made negative, faint sparks about 1 millim. long could be drawn by the finger from *c*; but when *d* was made positive the sparks from *c* were 10 millims. long. The same results are obtained when the finger is brought near *a*, so long as *c* remains insulated. If, however, *c* be connected with earth by a wire, no sparks can be got from *a*, whichever way the current passes between *b* and *d*. Connecting *a* with earth diminishes the length of the sparks, which can be drawn from *c* by about one-half.

The poles *a* and *b* being connected with the coil and the idle poles *c* and *d* having loose wires hanging from them, the wires were strongly repelled from each other.

The above experiments show that an idle pole in the direct line between the positive and the negative poles, and consequently receiving the full impact of the molecules driven from the negative pole, has a strong positive charge.

It now became of interest to ascertain whether the trajectory of the molecules suffered any deflection in passing an idle pole when it was suddenly uninsulated by an earth contact. For this purpose I used the tube described in a former paper,[1] where the shadow of an aluminium star was projected on a plate of phosphorescent glass. So long as the aluminium star is insulated, the shadow is sharp, as already described; but on touching the star to earth, the shadow widens out, forming a tolerably well-defined penumbra outside the original shadow, which can still be seen unchanged in size and intensity. On removing the earth connection, the penumbra disappears, the umbra remaining as before. The same penumbra is produced by connecting the idle pole with the negative pole through a very high resistance, such as a piece of wet string, instead of connecting it with earth. On bringing a magnet near the negative pole, the shadow of the (insulated) star is much increased in definition, the adjacent luminous parts of the screen becoming more luminous. Touching the star now brings a large, somewhat blurred, penumbra round the original image. The penumbra obeys the magnet the same as the umbra.

The aluminium star was now made the positive pole, the other pole remaining unchanged. The shadow of the star was projected on the phosphorescent plate of the same sharpness and almost the same intensity of light and shade as if the positive pole had been the one ordinarily used as such. The image obeyed the magnet as usual. With this arrangement the penumbral action could not be tested.

This, therefore, confirms the above-described results—that the idle pole, the shadow of which is cast by the negative pole, has strong positive charge. Now the stream of molecules must be assumed to carry negative electricity; when they actually strike the idle pole they are arrested, but those which graze the edge are attracted inwards by the positive electricity, and form the shadow. When the idle pole is connected with earth its potential would become zero were the discharge to cease; but, inasmuch as a constant positive charge is kept up from the passage of the current through the tube, we must assume that the potential of the uninsulated idle pole is still sufficiently positive to neutralise the negative charge which the impinging molecules would give it, and leave some surplus of positive. The effect of alternately uninsulating and insulating the idle pole is therefore to vary its positive electricity between considerable limits, and consequently its attractive action on the molecules which graze its edge.[2]

Experiments were tried with an idle pole and shadow tube whilst the exhaustion was going on. At such a rarefaction that the shadow can just be made out, it is quite sharp; touching the idle pole causes a small penumbra to appear round its shadow. When the exhaustion is at the best point for obtaining the green phosphorescence on the glass, the shadow is very sharp and well defined; and connecting the idle pole with earth gives a much wider penumbra, the width of the penumbra increasing with the degree of rarefaction. When the

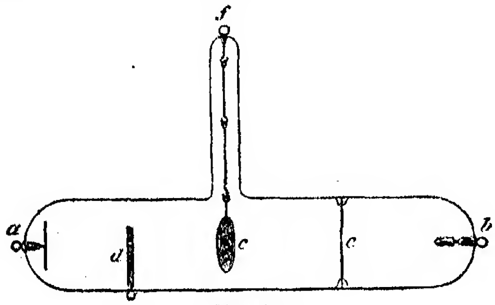
[1] *Phil. Trans.*, 1879, vol. 170, p. 147.

[2] I am aware that the theory which makes these effects of deflection depend on electrostatic attractions and repulsions is open to some grave objections; still it was that which in a great measure guided me in my experiments, and it could not well be omitted without reducing the description of them to a dry record of apparently unconnected facts.

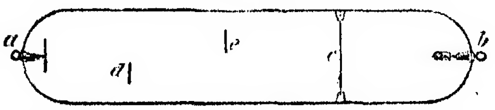
vacuum is so high that the spark has difficulty in passing, the penumbra (which becomes visible on insulating the idle pole) is much wider than before, and apparently eight or ten times as wide as it was at the lowest exhaustion at which observations were taken.

If the object whose shadow is cast on the screen is a non-conductor (such as a piece of glass rod), its shadow remains constant at all exhaustions, no penumbra being visible, as it cannot be uninsulated.

Prof. Stokes, whose suggestions throughout the course of this research have been most valuable, considered that much information might be gained by experimenting with an apparatus constructed in the following manner: the two poles of the tube (Fig. 9) are at *a* and *b*. At *c* is a



Elevation.



Plan.

FIG. 9.

FIG. 9A. FIG. 9B. FIG. 9C.

fluorescent screen; *d* is a fixed bar of aluminium, and *e* is another aluminium bar hanging from a platinum pole *f*, by a metal chain. The bar and pendulum are on opposite sides of the horizontal axis of the tube, as shown in the plan, so that when properly exhausted and the pole *a* made negative, the shadows of bar and pendulum shall fall side by side on the screen, as shown in Fig. 9A. On swinging the pendulum, the shadow alternately overlaps and recedes from the shadow of the bar (Figs. 9B and 9C).

This apparatus was tried many times with an induction coil, and also with a Holtz machine; but the results were not sufficiently definite to render it safe to draw any inference from them. By the kindness of Mr. De La Rue I have lately had the opportunity of experimenting with his large chloride of silver battery, and the results now come out with great sharpness and with none of the flickering and indecision met with when working with an induction-coil.

The tube was so adjusted that the pendulum hung free, and a narrow line of molecular discharge passed between the edges of the bar and the pendulum, forming a line of light between the two shadows on the screen (Fig. 9A). When the pendulum was set swinging, and the idle pole *f* connected with it was kept insulated, the regular appearance of the moving and fixed shadows was very slightly interfered with. That is to say, the shadows followed the successive positions between those shown in Figs. 9B and 9C almost as if they had been cast by a luminous point in place of the negative pole. As the shadow of the swinging pendulum came very near that of the bar, the latter shadow seemed to shrink away, showing that the pendulum itself exerted slight repulsion on the molecules which passed close to its edge.

The pendulum was again set stationary, as shown on the plan (Fig 10), the line of light separating the two

FIG. 10.

being at *f*, so that the appearance on the screen was as shown at Fig. 9A. The pendulum pole was then connected with earth, and instantly the line of light which separated the poles moved from *f* to *g* through an angle, measured from *e*, of about 30°, the shadow widening out and getting indistinct at the same time.

When the pole *a* was negative and *b* positive, the bar *d* and pendulum *e* were each found to be positively electrified. The outside of the glass tube, both near the negative pole and near the positive pole, was also positively electrified.

The above experiments were tried with 6300 cells, a resistance equal to 800,000 ohms being interposed. The current through the tube was 0·00383 weber. These measurements were taken by Mr. De La Rue, to whom I am greatly indebted for permission to experiment with his magnificent battery, and who himself kindly assisted me in making the arrangements. WILLIAM CROOKES

(*To be continued.*)

ROCK-WEATHERING, AS ILLUSTRATED IN CHURCHYARDS[1]

COMPARATIVELY little has yet been done in the way of precise measurement of the rate at which the exposed surfaces of different kinds of rock are removed in the processes of weathering. A few years ago some experiments were instituted by Prof. Pfaff of Erlangen to obtain more definite information on this subject. He exposed to ordinary atmospheric influences carefully measured and weighed pieces of Solenhofen limestone, syenite, granite (both rough and polished), and bone. At the end of three years he found that the loss from the limestone was equivalent to the removal of a uniform layer 0·04 mm. in thickness from its general surface. The stone had become quite dull and earthy, while on parts of its surface fine cracks and incipient exfoliation had appeared.[2] The time during which the observations were continued is however too brief to allow any general deductions to be drawn from them as to the real average rate of disintegration. Prof. Pfaff relates that during the period a severe hailstorm broke one of the plates of stone. An exceptionally powerful cause of this nature might make the loss during a short interval considerably greater than the true average of a longer period.

It occurred to me recently that data of at least a provisional value might be obtained from an examination of tombstones freely exposed to the air in graveyards in cases where their dates remained still legible or might be otherwise ascertained. I have accordingly paid attention to the older burial-grounds in Edinburgh, and have gathered together some facts which have perhaps sufficient interest and novelty to be communicated to the Society.

At the outset it is of course obvious that in seeking for

[1] A Paper read to the Royal Society of Edinburgh, on April 19, by Prof. Geikie, F.R.S.

[2] "Allgemeine Geologie als exacte Wissenschaft," p. 317.

data bearing on the general question of rock-weathering we must admit the kind and amount of such weathering visible in a town to be in some measure different from what is normal in nature. So far as the disintegration of rock-surfaces is effected by mineral acids, for example, there must be a good deal more of such chemical change where sulphuric acid is copiously evolved into the atmosphere from thousands of chimneys than in the pure air of country districts. In these respects we may regard the disintegration in towns as an exaggeration of the normal rate. Still the difference between town and country may be less than might be supposed. Surfaces of stone are apt to get begrimed with dust and smoke, and the crust of organic and inorganic matter deposited upon them may in no small measure protect them from the greater chemical activity of the more acid town rain. In regard to the effect of daily or seasonal changes of temperature, on the other hand, any difference between town and country may not impossibly be on the side of the town. Owing probably to the influence of smoke in retarding radiation, thermometers placed in open spaces in town commonly mark an extreme nocturnal temperature not quite so low as those similarly placed in the suburbs, while they show a maximum day temperature not quite so high.

The illustrations of rock-weathering presented by city graveyards are necessarily limited to the few kinds of rock employed for monumental purposes. In this district the materials used are of three kinds: 1st, Calcareous, including marbles and limestones; 2nd, Sandstones and flagstones; 3rd, Granites.

I. CALCAREOUS.—With extremely rare exceptions, the calcareous tombstones in our graveyards are constructed of ordinary white saccharoid Italian marble. I have also observed a pink Italian shell-marble and a finely fossiliferous limestone containing fragments of shells, foraminifera, &c.

In a few cases the white marble has been employed by itself as a monolith in the shape of an obelisk, urn, or other device; but most commonly it occurs in slabs which have been tightly fixed in a framework of sandstone. These slabs, from less than one to fully two inches thick, are generally placed vertically; in one or two examples they have been inserted in large horizontal sandstone slabs or "through-stanes." The form into which it has been cut and the position in which it has been erected have had considerable influence on the weathering of the stone.

A specimen of the common white marble employed for monumental purposes was obtained from one of the marble works of the city, and examined microscopically. It presented the well-known granular character of true saccharoid marble, consisting of rounded granules of clear transparent calcite, averaging about $\frac{1}{100}$ inch in diameter. Each granule has its own system of twin lamellations, and not unfrequently gives interference colours. The fundamental rhombohedral cleavage is everywhere well developed. Not a trace exists of any amorphous granular matrix or base holding the crystalline grains together. These seem moulded into each other, but have evidently no extraordinary cohesion. A small fragment placed in dilute acid was entirely dissolved. There can be no doubt that this marble must be very nearly pure carbonate of lime.

The process of weathering in the case of this white marble presents three phases, sometimes to be observed on the same slab, viz., Superficial Solution, Internal Disintegration, and Curvature with Fracture.

(1) *Superficial solution* is effected by the carbonic acid and partly by the sulphuric acid of town rain. When the marble is first erected it possesses a well-polished surface capable of affording a distinct reflection of objects placed in front of it. Exposure for not more than a year or two to our prevalent westerly rains suffices to remove this polish, and to give the surface a rough granular character. The granules which have been cut across or bruised in the cutting and polishing process are first attacked, and removed in solution or drop out of the stone. An obelisk in Greyfriars churchyard erected in memory of a lady who died in 1864 has so rough and granular a surface that it might readily be taken for a sandstone. So loosely are the grains held together that a slight motion of the finger will rub them off. In the course of solution and removal the internal structure of the marble begins to reveal itself. Its harder nests and veinings of calcite and other minerals project above the surrounding surface, and may be traced as prominent ribs and excrescences running across the faint or illegible inscriptions. On the other hand some portions of the marble are more rapidly removed than others. Irregular channels, dependent partly on the direction given to trickling rain by the form of the monumental carving, but chiefly on original differences in the internal structure of the stone, are gradually hollowed out. In this way the former artificial surface of the marble disappears, and is changed into one that rather recalls the bare, bleached rocks of some mountain side.

The rate at which this transformation takes place seems to depend primarily on the extent to which the marble is exposed to rain. Slabs which have been placed facing to north-east, and with a sufficiently projecting architrave to keep off much of the rainfall, retain their inscriptions legible for a century or longer. But even in these cases the progress of internal disintegration is distinctly visible. Where the marble has been less screened from rain the rapidity of waste has been sometimes very marked. A good illustration is supplied by the tablet of G—— G——, on the south side of Greyfriars Churchyard, who died in 1785.[1] This monument had become so far decayed as to require restoration in 1803. It is now, and has been for some years, for the most part utterly illegible. The marble has been dissolved away over the centre of the slab to a depth of about a quarter of an inch. Yet this monument is by no means in an exposed situation. It faces eastward in a rather sheltered corner, where, however, the wind eddies in such a way as to throw the rain against the part of the stone which has been most corroded.

In the majority of cases superficial solution has been retarded by the formation of a peculiar grey or begrimed crust, to be immediately described. The marble employed here for monumental slabs appears to be peculiarly liable to the development of this crust. Another kind of white marble, sometimes employed for sculptured ornaments on tombstones, dissolves without crust. It is snowy white, and more translucent than the ordinary marble. So far as the few weathered specimens I have seen enable me to judge, it appears to be either Carrara marble or one of the strongly saccharoid, somewhat translucent varieties employed instead of it. This stone, however, though it forms no crust, suffers marked superficial solution. But it escapes the internal disintegration which, so far as I have observed, is always an accompaniment of the crust. But the few examples of it I have met with hardly suffice for any comparison between the varieties.

(2) *Internal Disintegration.*—Many of the marble monuments in our older churchyards are covered with a dirty crust, beneath which the stone is found on examination to be merely a loose crumbling sand. This crust seems to form chiefly where superficial solution is feeble. It may be observed to crack into a polygonal network, the individual polygons occasionally curling up so as to reveal the yellowish white crumbling material underneath. It also rises in blisters, which, when they break, expose the interior to rapid disintegration.

So long as this begrimed film lasts unbroken the smooth face of the marble slab remains with apparently little modification. The inscription may be perfectly

[1] For obvious reasons I withhold the names carved on the tombstones referred to in this communication.

legible; the moment the crust is broken up, however, the decay of the stone is rapid. For we then see that the cohesion of the individual crystalline granules of the marble has already been destroyed, and that the merest touch causes them to crumble into a loose sand.

It appears therefore that two changes take place in upright marble slabs freely exposed to rain in our burial-grounds—a superficial, more or less firm crust is formed, and the cohesion of the particles beneath is destroyed.

The crust varies in colour from a dirty grey to a deep brown black, and in thickness from that of writing-paper up to sometimes at least a millimetre. One of the most characteristic examples of it was obtained from an utterly decayed tomb (erected in the year 1792), on the east side of Canongate Churchyard. No one would suppose that the pieces of flat dark stone lying there on the sandstone plinth were once portions of white marble. Yet a mere touch suffices to break the black crust, and the stone at once crumbles to powder. Nevertheless the two opposite faces of the original polished slab have been preserved, and I even found the sharply-chiselled socket-hole of one of the retaining nails. The specimen was carefully removed and soaked in a solution of gum, so as to preserve it from disintegration. On submitting the crust of the marble to microscopic investigation, I found it to consist of particles of coal, grains of quartz sand, angular pieces of broken glass, fragments of red brick or tile, and organic fibres. This miscellaneous collection of town dust was held together by some amorphous cement which was not dissolved by hydrochloric acid. At my request my friend Mr. B. N. Peach tested it with soda on charcoal, and at once obtained a strong sulphur reaction. There can be little doubt that it is mainly sulphate of lime. The crust which forms upon our marble tombstones is thus a product of the reaction of the sulphuric acid of the town rain upon the carbonate of lime. A pellicle of amorphous gypsum is deposited upon the marble and incloses the particles of dust which give the characteristic sooty aspect to the stone. This pellicle, of course, when once formed, is comparatively little affected by the chemical activity of rain-water. Hence the conservation of the even surface of the marble. It is liable, however, to be cracked by an internal expansion of the stone to which I shall immediately refer, and also to rise in small blisters, and as I have said, its rupture leads at once to the rapid disintegration of the monument.

The cause of this disintegration is the next point for consideration. Chemical examination revealed the presence of a slight amount of sulphate in the heart of the crumbling marble; but the quantity appeared to me to be too small seriously to affect the cohesion of the stone. I submitted to microscopic examination a portion of a crumbling urn of white marble in Canongate Churchyard. The tomb bears a perfectly fresh date of "1792" cut in sandstone over the top; but the marble portions are crumbling into sand, though the structure faces the east, and is protected from vertical rain by arching mason-work. A small portion of the marble retaining its crust was boiled in Canada balsam, and was then sliced at right angles to its original polished surface. By this means a section of the crumbled marble was obtained which could be compared with one of the perfectly fresh stone. From the dark outer amorphous crust with the carbonaceous and other miscellaneous particles fine rifts could be seen passing down between the separated calcite granules, which in many cases were quite isolated. The black crust descends into these rifts, and likewise passes along the cleavage planes of the granules. Towards the outer surface of the stone immediately beneath the crust the fissures are chiefly filled with a yellowish, structureless substance, which gave a feeble glimmering reaction with polarised light, and inclosed minute amorphous aggregates like portions of the crust. It probably consists chiefly of sulphate of lime. But the most remarkable feature in the slide was the way in which the calcite granules had been corroded. Seen with reflected light, they resembled those surfaces of spar which have been placed in weak hydrochloric acid to lay bare inclosed crystals and zeolites. The solution had taken place partly along the outer surfaces, so as to produce the fine passage or rifts, and partly along the cleavage. Deep cavities, defined by intersecting cleavage planes, appeared to descend into the heart of some of the granules. In no case did I observe any white pellicle such as might indicate a redeposit of lime from the dissolved carbonate. Except for the veining of probable sulphate just referred to, the lime when once dissolved had apparently been wholly removed in solution. There was further to be observed a certain dirtiness, so to speak, which at the first glance distinguished the section of crumbled marble from the fresh stone. This was due partly to corrosion, but chiefly to the introduction of particles of soot and dust, which could be traced among the interstices and cleavage lamellæ of the crystalline granules, for some distance back from the crust.

It may be inferred, therefore, that the disintegration of the marble is mainly due to the action of carbonic acid in the permeating rain-water, whereby the component crystalline granules of the stone are partially dissolved and their mutual adhesion is destroyed. This process goes on in all exposures, and with every variety in the thickness of the outer crust. It is distinctly traceable in tombstones that have not been erected for more than twenty years. In those which have been standing for a century it is, save in exceptionally sheltered positions, so far advanced that a very slight pressure suffices to crumble the stone into powder. But with this internal disintegration we have to take into consideration the third phase of weathering to which I have alluded. In the upright marble slabs it is the union of the two kinds of decay which leads to so rapid an effacement of the monuments.

3. *Curvature and Fracture.*—This most remarkable phase of rock-weathering is only to be observed in the slabs of marble which have been firmly inserted into a solid framework of sandstone and placed in an erect or horizontal position. It consists in the bulging out of the marble, accompanied with a series of fractures. The change cannot be explained as mere sagging by gravitation, for it usually appears as a swelling up of the centre of the slab, which continues until the large, blister-like expansion is disrupted. Nor is it by any means exceptional; it occurs as a rule on all the older upright marble tablets, and is only found to be wanting in those cases where the marble has evidently not been fitted tightly into its sandstone frame. Wherever there has been little or no room for expansion, protuberance of the marble may be observed. Successive stages may be seen, from the first gentle uprise to an unsightly swelling of the whole stone. This change is accompanied by fracture of the marble. The rents in some cases proceed from the margin inwards, more particularly from the upper and under edges of the stone, pointing unmistakably to an increase in volume as the cause of fracture. In other cases the rents appear in the central part of the swelling, where the tension from curvature has been greatest.

Some exceedingly interesting examples of this singular process of weathering are to be seen in Greyfriars Churchyard. On the south wall, in the inclosure of a well-known county family, there is an oblong upright marble slab measuring 30¼ inches in height by 22⅜ inches in breadth, and ⅞ inch in thickness, facing west. The last inscription on it bears the date 1838, at which time it was no doubt still smooth and upright. Since then, however, it has escaped from its fastenings on either side, though still held firmly at the top and bottom. It consequently projects from the wall like a well-filled sail. The axis of curvature is of course parallel to the upper and lower margins, and the

amount of curvature from the original vertical line is fully $2\frac{1}{8}$ inches, so that the hand and arm can be inserted between the curved marble and the perfectly vertical and undisturbed wall to which it was fixed. At the lower end of this slab a minor curvature, to the extent of $\frac{1}{8}$ inch, is observable coincident with the longer axes of the stone. In both cases the direction of the bending has been determined by the position of the inclosing solid frame of sandstone which resisted the internal expansion of the marble. Freed from its fastenings at either side, the stone has assumed a simple wave-like curve. But the tension has become so great that a series of rents has appeared along the crest of the fold. One of these has a breadth of $\frac{1}{10}$ inch at its opening.[1] Not only has the slab been ruptured, but its crust has likewise yielded to the strain, and has broken up into a network of cracks, and some of the isolated portions are beginning to curl up at the edges, exposing the crumbling, decayed marble below. I should add that such has been the expansive force of the marble that the part of the sandstone block in the upper part of the frame exposed to the direct pressure has begun to exfoliate, though elsewhere the stone is quite sound.

More advanced stages of curvature and fracture may be noticed on many other tombstones in the same burying-place. One of the most conspicuous of these has a peculiar interest from the fact that it occurs on the tablet erected to the memory of one of the most illustrious dead whose dust lies within the precincts of the Greyfriars—the great Joseph Black. He died in 1799. In the centre of the sumptuous tomb raised over his grave is inserted a large upright slab of white marble, which, facing south, is protected from the weather partly by heavy overhanging masonry, and partly by a high stone wall immediately to the west. On this slab a Latin inscription records with pious reverence the genius and achievements of the discoverer of carbonic acid and latent heat, and adds that his friends wished to mark his resting-place by the marble whilst it should last. Less than eighty years, however, have sufficed to render the inscription already partly illegible. The stone, still firmly held all round its margin, has bulged out considerably in the centre, and on the blister-like expansion has been rent by numerous cracks which run on the whole in the direction of the length of the stone.

A further stage of decay is exhibited by a remarkable tomb on the west wall of the Greyfriars Churchyard. The marble slab, bearing a now almost wholly effaced inscription, on which the date 1779 can be seen, is still held tightly within its inclosing frame of sandstone slabs, which are firmly built into the wall. But it has swollen out into a ghastly protuberance in the centre, and is moreover seamed with rents which strike inwards from the margins. In this and in some other examples the marble seems to have undergone most change on the top of the swelling, partly from the system of fine fissures by which it is broken up, and partly from more direct and effective access of rain. Eventually the cohesion of the stone at that part is destroyed, and the crumbling marble falls out, leaving a hole in the middle of the slab. When this takes place disintegration proceeds rapidly. Three years ago I sketched a tomb in this stage on the east wall of Canongate Churchyard. In a recent visit to the place I found that the whole of the marble had since fallen out.

The first cause that naturally suggests itself in explanation of this remarkable change in the structure of a substance usually regarded as so inelastic is the action of frost. White statuary marble is naturally porous. It is rendered still more so by that internal solution which I have described. The marble tombstones in our graveyards are therefore capable of imbibing a relatively large amount of moisture. When this interstitial water is frozen its expansive force as it passes into the solid state must increase the isolation of the granules and augment the dimensions of a marble block. I am inclined to believe that this must be the principal cause of the change. Whatever may be the nature of the process, it is evidently one which acts from within the marble itself. Microscopic examination fails to discover any chemical transformation which would account for the expansion. Dr. Angus Smith has pointed out that in towns the mortar of walls may be observed to swell up and lose cohesion from a conversion of its lime into the condition of sulphate. I have already mentioned that sulphate does exist within the substance of the marble, but that its quantity so far as I have observed is too small to be taken into account in this question. The expansive power is exerted in such a way as not sensibly to affect the internal structure and composition of the stone, and this I imagine is most probably the work of frost.

The results of my observations among our burial grounds show that, save in exceptionally sheltered situations, slabs of marble exposed to the weather in such a climate and atmosphere as that of Edinburgh are entirely destroyed in less than a century. When this destruction takes place by simple comparatively rapid superficial solution and removal of the stone, the rate of lowering of the surface amounts sometimes to about a third of an inch (or roughly nine millimetres) in a century. Where it is effected by internal displacement, a curvature of two and a half inches with abundant rents, a partial effacement of the inscription and a reduction of the marble to a pulverulent condition may be produced in about forty years, and a total disruption and effacement of the stone within one hundred. It is evident that white marble is here utterly unsuited for out-of-door use, and that its employment for really fine works of art which are meant to stand in the open air in such a climate ought to be strenuously resisted. Of course I am now referring not to the durability of marble generally, but to its behaviour in a large town with a moist climate and plenty of coal smoke.

II. SANDSTONES AND FLAGSTONES.—These, being the common building materials of the country, are of most frequent occurrence as monumental stones. When properly selected, they are remarkably durable. By far the best varieties are those which consist of a nearly pure fine siliceous sand, with little or no iron or lime, and without trace of bedding structure. Some of our sandstones contain 98 per cent. of silica. A good illustration of their power of resisting the weather is supplied by Alexander Henderson's tomb in Greyfriars Churchyard. He died in 1646, and a few years afterwards the present tombstone, in the form of a solid square block of freestone, was erected at his grave. It was ordered to be defaced in 1662 by command of the Scottish Parliament, but after 1688 it was repaired. Certain bullet marks upon the stone are pointed out as those of the soldiery sent to execute the order. Be this as it may, the original chisel marks on the polished surface of the stone are still perfectly distinct, and the incised lettering remains quite sharp. Two hundred years have effected hardly any change upon the stone, save that on the west and south sides, which are those most exposed to wind and rain, the surface is somewhat roughened, and an internal fine parallel jointing begins to show itself.

Three obvious causes of decay in arenaceous rocks may be traced among our monuments. In the first place, the presence of a soluble or easily removable matrix in which the sand grains are embedded. The most common kinds of matrix are clay, carbonates of lime and iron, and the anhydrous and hydrous peroxides of iron. The presence of the iron reveals itself by its yellow, brown, or red colour. So rapid is disintegration from this cause, that the sharply-incised date of a monument

[1] It is a further curious fact that the slab measures half an inch more in breadth across the centre where it has had room to expand than at the top where it has been tightly jammed between the sandstone slabs.

erected in Greyfriars Church to an officer who died only in 1863 is no longer legible. At least $\frac{1}{8}$th of an inch of surface has here been removed from a portion of the slab in sixteen years, or at the rate of about $\frac{3}{4}$ inch in a century.

In the second place, where a sandstone is marked by distinct laminæ of stratification, it is nearly certain to split up along these lines under the action of the weather if the surface of the bedding planes is directly exposed. This is well known to builders, who are quite aware of the importance of "laying a stone on its bed." Examples may be observed in our churchyards, where sandstones of this character have been used for pilasters and ornamental work, and where the stone set on its edge has peeled off in successive layers. In flagstones, which are merely thinly-bedded sandstones, this minuter lamination is fatal to durability. These stones, from the large size in which slabs of them can be obtained and from the ease with which they can be worked, form a tempting material for monumental inscriptions. The melancholy result of trusting to their permanence is strikingly shown by a tombstone at the end of the South Burying Ground in Greyfriars Churchyard. The date inscribed on it is 1841, and the lettering that remains is as sharp as if cut only recently. The stone weathers very little by surface disintegration. It is a laminated flagstone set on edge, and large portions have scaled off, leaving a rough, raw surface where the inscription once ran. In this instance a thickness of about $\frac{1}{5}$ inch has been removed in forty years.

In the third place, where a sandstone contains concretionary masses of different composition or texture from the main portion of the stone, these are apt to weather at a different rate. Sometimes they resist destruction better than the surrounding sandstone, so as to be left as prominent excrescences. More commonly they present less resistance, and are therefore hollowed out into irregular and often exceedingly fantastic shapes. Examples of this kind of weathering abound in our neighbourhood. Perhaps the most curious to which a date can be assigned are to be found in the two sandstone pillars which until recently flanked the tomb of Principal Carstares in Greyfriars Churchyard. They were erected some time after the year 1715. Each of them is formed of a single block of stone about 8 feet long. Exposure to the air for about 150 years has allowed the original differences of texture or composition to make their influence apparent. Each is hollowed out for almost its entire length on the exposed side into a trough 4 to 6 inches deep and 6 to 8 inches broad. As they lean against the wall beneath the new pillars which have supplanted them, they suggest some rude form of canoe rather than portions of a sepulchral monument.

Where concretions are of a pyritous kind, their decomposition gives rise to sulphuric acid, some of which combines with the iron and gives rise to dark stains upon the corroded surface of the stone. Some of the sandstones of this district, full of such impurities, ought never to be employed for architectural purposes. Every block of stone in which they occur should be unhesitatingly condemned. Want of attention to this obvious rule has led to the unsightly disfigurement of public buildings.

III. GRANITES.—In Prof. Pfaff's experiments, to which I have already referred, he employed plates of syenite and granite, both rough and polished. He found that they had all lost slightly in weight at the end of a year. The annual rate of loss was estimated by him as equal to 0·0076 mm. from the unpolished and 0·0085 from the polished granite. That a polished surface of granite should weather more rapidly than a rough one is perhaps hardly what might have been expected. The same observer remarks that though the polished surface of syenite was still bright at the end of not more than three years, it was less so than at first, and in particular that some figures indicating the date which he had written on it with a diamond had become entirely effaced. Granite has been employed for too short a time as a monumental stone in our cemeteries to afford any ready means of measuring even approximately its rate of weathering. Traces of decay in some of its felspar crystals may be detected, yet in no case that I have seen is the decay of a polished granite surface sensibly apparent after exposure for fifteen or twenty years. That the polish will disappear, and the surface will gradually roughen as the individual component crystals are more or less easily attacked by the weather, is of course sufficiently evident. Even the most durable granite will probably be far surpassed in permanence by the best of our siliceous sandstones. But as yet the data do not exist for making any satisfactory comparison between them.

GERHARD JOHANNES MULDER

IN the death of Prof. G. J. Mulder, to which we briefly alluded in our last number, Holland has been called upon to mourn the loss of her leading chemist. Gerhard Johannes Mulder was born at Utrecht, December 27, 1802. His studies were completed at the university of his native city, and embraced especially mathematics, the natural sciences, and medicine. In 1825 he established himself as physician at Amsterdam. His inclination towards a more purely scientific career caused him however in the year following to accept a position as teacher of physics at Rotterdam under the auspices of the Batavian Society. This proved but the stepping-stone to the Professorship of Botany and Chemistry at the Rotterdam Medical School, to which he was appointed in 1827. In 1841 he accepted a call to the Chair of Chemistry at Utrecht, and returned to the place of his birth, to add to its fame by making it the scene of a long-continued series of valuable chemical researches.

Mulder's tastes lay almost entirely in the department of organic chemistry, and more especially in those branches connected with the phenomena of vegetable and animal life. In mineral chemistry his researches were confined to careful studies on the chemical composition of white lead and red lead (1839)—two of the important technical products of Holland—and to the establishment of the atomic weight of tin (1849) by means of numerous analyses. He also modified or perfected a number of analytical methods, such as those for the determination of silver, phosphorus, carbonic acid, &c., and contributed a large variety of analytical data on various technical and scientific compounds. In 1864 he made an elaborate investigation on the phenomena of solution of salts in water, establishing several of the now generally accepted laws with regard to the solubility of mixtures of salts, among others the interesting fact that in saturated solutions of mixtures the relations between the respective quantities of the salts is expressed in multipla of their molecular weights. The varied experimental data resulting from his own researches were grouped, together with the contributions of other chemists on this subject, in the form of a monograph of over 300 pages, which forms the most important work extant on solubility.

In physiological chemistry Mulder has conducted a large variety of investigations. The most important are those connected with the study of the albuminoids, which were commenced in 1838 and extended over a period of twenty years. In the course of these investigations he exposed albumin, fibrine, caseïne, &c., to the action of a variety of chemical agents, obtaining the products of oxidation, chlorination, nitrification, &c. At an early date he obtained, by the action of alkaline solutions on the albuminoids, the so-called *protein*, which he regarded as the primary albuminoid matter, the various members of the group consisting of this radical in union with small quantities of sulphur, phosphorus, and oxygen. This

ingenious hypothesis, while being a fruitful cause of research, was ultimately found to be untenable. It involved the author in a somewhat bitter discussion with Liebig and his school, who finally proved proteïn to be by no means a homogeneous body, and to contain a notable quantity of sulphur, in opposition to Mulder's opinion. While failing to solve the problem of the constitution of this group of compounds, a problem which, even despite Schützenberger's remarkable experiments during the past few years, is but half-way toward solution, Mulder vastly increased our knowledge of the proteïds by numerous analytical results and thorough studies of the chemical properties of the different members of the group and of their derivatives. As especially interesting papers in this connection should be mentioned his research on the nature of the albuminoid forming the crystalline lens of the eye (1839), and that on the natural and artificial formation of peptone from the albuminoids (1858). Closely allied to this subject were the important researches on chondrine and other gelatinous bodies carried out in 1839. From this same year dates also his extended investigation of the chemical properties of hematin, the colouring matter of the blood. The examination of blood enlisted his attention at various intervals, and led to numerous analytical tests, to one of which we owe the proof of the presence of carbonic acid as a normal constituent of the blood. In addition to the topics alluded to, Mulder has contributed to physiological chemistry a large variety of minor isolated observations and numerous analyses of various products of the animal economy.

In the chemistry of vegetable physiology he developed a scarcely less noteworthy activity and diversity. In 1839 and 1840 were published important papers on inulin and starch, and on pectin and pectic acid. At the same time appeared his analytical investigations on the composition of silk, of gum arabic and other gums, of the poison of the upas, of various sorts of tea and coffee, of tannic acid, of numerous ethereal oils, of the resinous matter in turf, of salicin and phlorizin, and of the compounds rufin and rutilene, derived from them, and of gluten. In 1839 he published an extensive research on cassia-oil and cinnamon-oil, and on benzone, in which numerous derivatives of these bodies are described. In the year following he completed an elaborate investigation on the ulmic bodies, which forms the chief basis of our knowledge in this still comparatively obscure field. This was followed by interesting researches on yeast (1844), on chlorophyll, on the presence of waxy constituents in many ordinary plants (1844), on the action of acids on woody fibre (1846), on chrysamonic acid and other derivatives from aloes. In 1865 he published a very complete and valuable study on drying oils and their chemical properties, based on a wide range of experimental observation. Mulder made two important contributions to the special chemistry of the aromatic compounds by his discovery in 1839 of meta-nitro-benzoic acid—one of the earliest representatives of the nitro acids—and by his study in 1858 on the formation of picric acid from indigo, in which he advanced the now generally accepted opinion of a transition, by means of isatin and nitro-salicylic acid, from one compound to the other. Organic chemistry is likewise indebted to him for several improvements in analytical methods, and he was one of the first to devise gas furnaces for use in organic combustions.

As an author and editor Prof. Mulder was scarcely less active than as an investigator. His principal works, which are better known in their German translations, are:—"Proeve eener allgemeene physiologische Scheikunde" (1843), translated into German by Prof. Kolbe, under the title of "Versuch einer allgemeinen physiologischen Chemie;" "Die Ernährung in ihrem Zusammenhang mit dem Volksgeist" (1847); "Die Chemie des Weins" (1856); "Die Chemie des Biers" (1858); "Die Silberprobirmethode" (1859); "Die Chemie der Ackerkrume," 3 vols. (1864); "Beiträge zur Geschichte des chemisch gebundenen Wassers" (1864); "Die Chemie der austrockenden Oele" (1867). As an editor he published, in connection with Van Hall and Vrolik, the "Bijdragen tot de natuurkundige wetenschappen" from 1826 to 1832. During the six years following he edited the "Natuur- en scheikundige Archief." After uniting for several years with Miquel and Wenckeback in the editorship of the "Bulletin des Sciences physiques et naturelles en Néerlande," he has issued since 1842 the "Scheikundige Verhandelingen en Onderzoekingen" (Rotterdam), the only chemical journal of Holland.

Prof. Mulder was frequently intrusted by his Government with important commissions, and has contributed greatly by his pen and speech to the cultivation of chemistry in Holland. In 1860 he was elected an honorary member of the London Chemical Society. T. H. N.

NOTES

A considerable number of the Fellows of the Royal Society have decided to add a portrait of Sir Joseph Hooker to the valuable collection of historical portraits belonging to the Society, and they invite others to join in the subscription. Cheques crossed "Barclay and Co., for the Sir J. Hooker Portrait Fund," to be paid to Messrs. Barclay and Co., 54, Lombard Street, E.C.

At the last meeting of the Chemical Society it was announced that the Longstaff Medal had been awarded to Prof. Thorpe, of the Yorkshire College, Leeds. Prof. Thorpe is the first recipient of the medal.

On Sunday, May 23, M. Dumas was presented by the Société d'Encouragement with a civic crown, in acknowledgment of the services rendered to science and to France during more than half a century.

The Emperor of Germany has appointed Prof. Baron von Nordenskjöld a foreign Knight of the Ordre pour le Mérite for Arts and Sciences.

The Visitation of the Royal Observatory takes place on Saturday.

The funds for the erection of a monument in memory of the great philosopher, Leibnitz, at Leipzig, have now reached the sum considered necessary, and Prof. Hänel of Dresden is about to execute the monument. It will be erected on the southern side of the St. Thomas Churchyard. The statue of Leibnitz will be of bronze, and will measure 3½ metres in height. The pedestal will have the same height, and will be adorned by four bas reliefs.

We have to record the death of Mr. Alfred Swaine Taylor, F.R.S., the physician and toxicologist. He was born at Northfleet, Kent, in December, 1806. He was a pupil of Sir Astley Cooper and Mr. J. H. Green at Guy's Hospital, and afterwards studied in the leading medical schools of France, Germany, and Italy. In 1830 he entered the Royal College of Surgeons, was admitted a Licentiate of the Royal College of Physicians in 1848, and was elected a Fellow of the same five years later. In 1845 he was chosen a Fellow of the Royal Society. He was the first holder of the chair of Medical Jurisprudence in Guy's Hospital, and was for many years joint-Professor, and subsequently sole Professor, of Chemistry. Dr. Swaine Taylor was the author of several professional treatises, more especially on the subjects of poisons and poisonings, chemistry, and medical jurisprudence; and he had received the honorary degree of M.D. from the University of St. Andrew's.

On May 15 the Congress of Bohemian Naturalists was opened at Prague. Dr. Albert, of Innsbruck University, was elected

president. Prof. Krejczi, a geologist of repute, delivered an address in which he pointed out the importance of German natural science, rather a bold, and certainly commendable, thing to do in the somewhat narrow-minded Czech capital.

THE Swiss Natural History Society will hold its general meeting on September 12–15 next, in the small town of Brieg, in the canton Vaud, at the foot of the Simplon.

WE are pleased to hear that negotiations are in progress for the transfer of the Museum Godeffroy to the City of Hamburg. In it are to be found by far the finest series of the zoological and ethnographical products of the Pacific Islands yet assembled together, including, we believe, all the types of the new species described in the thirteen "Hefts" of the *Journal des Museum Godeffroy*. It would be a great misfortune to science if these were distributed all over the world by the auctioneer's hammer, so that it is much to be hoped that a satisfactory arrangement will be come to between the liquidators of the "Maison Godeffroi" and the citizens of Hamburg.

THE Emperor of Russia has conferred the Grand Cross of the Order of Stanislaus upon Dr. Hermann Obst, the director of the Ethnographical Museum of Leipzig.

WE would earnestly draw the attention of our readers to the fact that the Secretary of the Smithsonian Institution, Washington, U.S., of which Mr. James Smithson was the founder, is desirous of obtaining information respecting that gentleman to assist in the preparation of a memoir. James Smithson, F.R.S., was the son of Hugh, first Duke of Northumberland, and Elizabeth, heiress of the Hungerfords of Audley, and niece of Charles, Duke of Somerset. In 1826 he resided at Bentinck Street, Cavendish Square. He died in 1829. The following are some of the points on which information is desired:—"John Fitall, a trusted servant of Mr. James Smithson, died June 14, 1834, at Bush House, Wanstead, Essex, England. Have his heirs any relics or mementoes of Mr. Smithson—any notes, letters, &c.? Mr. Charles Drummond, a London banker, was the executor of Mr. Smithson. Can we procure originals or copies of any letters of Mr. Smithson from him? What do the records of the Royal Society say as to the election of James Lewis Macie as a Fellow? Perhaps a report was made to the Council as to his qualifications? What can be learned of the disagreement between Mr. Smithson and the Council of the Royal Society? Mr. Wheatstone knew of it. Do any of the surviving Members remember the circumstances? Information relative to Henry Louis Dickinson (half-brother of James Smithson), Colonel of the 84th Regiment of Foot. Information relative to the college life of James Lewis Macie, a graduate of May 26, 1786, of Pembroke College, Oxford University. Letters from James Smithson to Sir Humphrey Davy, Sir Davies Gilbert, Hon. Henry Cavendish, Dr. W. H. Wollaston, Mr. Smithson Tennant, Dr. Joseph Black, Dr. Hutton, M. Arago, M. Gay Lussac, M. Cordier, M. Haüy, M. Klaproth, M. A. C. Becquerel, M. Faujas de St. Fond, Mr. Thornton, Mr. Maclaire, Mr. Wm. Thomson; or any original letters of Mr. Smithson. Can the original manuscripts be found of Mr. Smithson's communications to the Royal Society or to Thomson's "Annals of Philosophy"? Can Mr. Smithson's authorship of papers or articles in any scientific journals be identified? What can be learned of Mr. Smithson's mother, Mrs. Macie? or of Col. Henry Louis Dickinson's mother, Mrs. Mary Ann Coates? At what number in Bentinck Street did Mr. Smithson reside? (He held apartments, was not a householder.) Had he at any time any other residence; if so, where?" Any information on the above points should be addressed to Prof. Spencer F. Baird, care of William Wesley, 28, Essex Street, Strand, London, the agent of the Smithsonian Institution.

MR. STORY MASKELYNE put his maiden question in Parliament the other evening very appropriately in connection with the Natural History Museum. Mr. Adam, in reply, stated that the trustees of the British Museum had been informed that they may now proceed to remove their collections to the new Natural History Museum. The question of providing residences for the officers of the museum was considered by the late Government, who did not see their way to comply with the request. At present, therefore, it is not contemplated that any such residences should be erected.

A DIFFICULTY has supervened in the St. Gothard tunnel, which, according to the *Times* correspondent, threatens seriously to retard the completion of the undertaking. In a part of it where the formation is a porous white stone the vaulting has already given way two or three times, and it has required the greatest care and constant staying with timber to prevent the passage thereabouts from completely collapsing. It was thought, however, that a granite wall 6 feet thick would be sufficiently strong to support the superincumbent mass of white stone and keep the tunnel permanently open. A wall of this thickness has just been finished, but it too has begun to give way, and the engineers are at their wits end how to overcome the difficulty. In the opinion of Dr. Stapf, the geologist of the tunnel, it can be overcome only by making a wide curve so as to get round the white stone instead of going through it. This would involve the entire reconstruction of that part of the tunnel, in which case it will probably not be ready for traffic before the time fixed for the completion of the lines of approach, two years hence.

MR. SETH GREEN, writing to the *New York World* of May 14, says that one morning when he was watching a spider's nest a wasp alighted within an inch or two of the nest, on the side opposite the opening. Creeping noiselessly around towards the entrance of the nest the wasp stopped a little short of it and for a moment remained perfectly quiet; then reaching out one of his antennæ he wiggled it before the opening and withdrew it. This overture had the desired effect, for the boss of the nest, as large a spider as one ordinarily sees, came out to see what was wrong and to set it to rights. No sooner had the spider emerged to that point at which he was at the worst disadvantage than the wasp, with a quick movement, thrust his sting into the body of his foe, killing him easily and almost instantly. The experiment was repeated on the part of the wasp, and when there was no response from the inside he became satisfied, probably, that he held the fort. At all events he proceeded to enter the nest and slaughter the young spiders, which were afterwards lugged off one at a time.

IN a series of papers on the northern part of the continent, contributed to an Australian paper under the somewhat odd title of "Northern Lights," the writer mentions a curious feature of the creeks and lagoons in the north of Queensland. This is what is called "floating grass." It is a tall aquatic grass, which, while growing in the mud when within reach, is quite independent in that respect, and extends its creeping stems into the deepest water; and by the interweaving of these, and of the roots emitted from every joint, makes a dense mat of verdure, which, at first sight, seems to have its origin on solid ground. It is however quite possible to walk on it without risk of entanglement. The method is to keep going, lifting the feet well, and with the body in as flat a position as possible. Horses and cattle are fond of this grass, and it is said that the masses of it are sometimes so dense, although with twenty feet of water underneath, that horses have been known to cross on them.

ON the French Eastern Railway Achard electric brakes are being tried, and are said to work satisfactorily. The electricity is not supplied by ordinary cells, but by Planté's accumulating battery.

A MEETING of the Epping Forest and County of Essex Naturalists' Field Club was held on Saturday, May 29, at Buck-

hurst Hill, when a lecture was delivered by Mr. Henry Walker, F.G.S., entitled "A Day's Elephant Hunting in Essex." At the conclusion of the lecture Sir Antonio Brady, who has taken an active interest in the formation of the Club, gave a detailed account of his method of removing and subsequently preserving the mammalian remains from the brick-earth pits at Ilford.

MR. C. S. SARGENT, Harvard Professor of Arboriculture, has published, in his capacity of special agent of the approaching United States census, a "Catalogue of the Forest Trees of North America," preliminary to one which will be added to the census report on the forest wealth of the United States. He desires information concerning the geographical range of any species, the most favourable region and elevation and geographical formation for its multiplication and perfection, its exceptionally large dimensions, its common or local name, and its products and uses.

THE number of persons who die from small pox is increasing daily in Paris. Statistics prove that 858 died in 1879, and not less than 1,038 in the four first months of 1880. This circumstance has created a great impression, and Dr. Liouville, in the Chamber of Deputies, has proposed a law to render vaccination compulsory. It has been reported upon favourably by the committee, and will accordingly in all probability soon become a part of the law of the land.

SEVERAL papers have stated that an official commission will be appointed in France to witness the crossing of the British Channel by a balloon travelling from France to England (weather permitting). The fact is that the experiment is to be made from Boulogne by M. Javis, with his own balloon and at his own risk. But the port authorities have agreed to send M. Javis such information as will enable him to select for starting a time when the wind is blowing with some sufficient prospect of reaching England. M. Javis will keep watch from June 1 to 20. A steamer will follow as far as possible the hardy aëronaut on his adventurous trip.

A BRANCH of the recently-founded Thüringer-Wald Club has been formed at Leipzig. A similar club, at present numbering twenty-five members, has been opened at Plauen (Saxony) with a view of promoting and furthering visits of tourists to the so-called Voigtland. The club will improve the roads, undertake excursions on a larger scale, see to the fixing of proper sign-posts, &c.

ON the shores of the Lake of Constance the rare phenomenon of a perfect solar halo was noticed on May 4 at noon. The large ring, which from time to time assumed splendid rainbow tints, remained visible for more than two hours. At Berlin the phenomenon of mock suns was observed on the 9th inst. at 8 a.m.

INTERESTING discoveries are reported from Italy. Near Este, in the Veneto, at the foot of the Euganean Mountains, Prof. Prosdocismi discovered a prehistoric burial-ground with many bronze and clay vessels. Eighty-two tombs were found, of which forty four seemed to have been opened already by the Romans, while the contents of the others seemed untouched. The urns belong to three different periods, some are stained black with linear ornaments, others are striped red and black. Some vases are of such exquisite workmanship that they could even to-day serve as patterns. A small case of bronze is adorned with human and animal figures.

M. VAROY, French Minister of Public Works, has visited in state the regional competition of Bar-le-Duc, and gave an address at a banquet. In this competition the most notable feature was the work done on a large field by a Gramme machine and a Fowler plough before the Minister and an immense crowd on May 23. The electric current also gave motion to some agricultural machines at a distance. This remarkable experiment was conducted by M. Felix, of Germase, a country place in the vicinity of Bar-le-Duc, where similar experiments on a smaller scale were made last year.

THE Twelfth and Thirteenth Annual Reports of American Archæology and Ethnology contain, as usual, several papers of great ethnological interest. From the Report of the curator, Mr. F. W. Putnam, it is evident that much excellent work continues to be done in the museum, which is rapidly becoming one of the most valuable repertories of ethnology in the world. The papers are all connected with American ethnology, the most important probably being that of Mr. Bandelier, on the Social Organisation and Mode of Government of the Ancient Mexicans.

THE *Proceedings* of the Davenport (U.S.) Academy of Natural Sciences, vol. i. part 2, while it contains a number of papers in natural history, is noteworthy mainly for the large number of papers on subjects connected with American ethnology, and chiefly on various mound explorations. We are pleased to see that this society continues to prosper; it had the originality to elect as its president for 1879 Mrs. Mary L. D. Putnam.

No. 4 of the Columbia College *School of Mines Quarterly* is better than ever, and we are glad to learn that it has successfully passed its brief probationary period, and is now regarded as an assured and unexpected success. Among the articles in this number are "Sanitary Problems of New York City," by Prof. Trowbridge; "Artificial Diamonds," by Mr. Lucius Pitkin; "Volumetric Analysis of Sulphuric Acid," by Mr. A. H. Elliott; "A New Planometer," by Mr. L. M. Hooper.

IN the *Transactions* of the Academy of Science of St. Louis, vol. iv. No. 1, are several papers deserving attention. Mr. N. Holmes has a specially interesting paper on the "Geological and Geographical Distribution of the Human Race," and students of the science of language will be interested in M. Coruna y Colludo's account of the Zoque language, spoken in the State of Chiapas, Mexico. There are two magnetic papers by Prof. Nipher, a paper on *Pentremites* by Dr. G. Hambach; on the genus *Pinus* by M. G. Engelmann, who has also a short paper on acorns and their germination.

As one of their "Occasional Papers" the Boston Society of Natural History have published a volume of great value on the "Geology of Eastern Massachusets," by Mr. W. O. Crosby. It is evidently the result of long and competent investigation, is well illustrated, and contains a large and well-printed geological map of the region treated of.

THE additions to the Zoological Society's Gardens during the past week include a Grey-cheeked Monkey (*Cercocebus albigena*) from West Africa, presented by the Earl of Lonsdale, F.Z.S.; a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, a Balearic Crowned Crane (*Balearica pavonina*) from West Africa, presented by Mr. Frank Simpson; two Cashmere Shawl Goats (*Capra hircus*) from India, presented by Dr. W. Taylor; an Alexandrine Parrakeet (*Palæornis alexandri*) from India, two West African Love Birds (*Agapornis pullaria*) from West Africa, a Common Raven (*Corvus corax*), European, a Crimson-eared Waxbill (*Estrelda phœnicotis*) from West Africa, presented by Mr. C. Williams; a South American Rat Snake (*Spilotes variabilis*) from Demerara, presented by Mr. G. H. Hawtayne, C.M.Z.S.; three Cashmere Shawl Goats (*Capra hircus*) from India, a Malbrouck Monkey (*Cercopithecus cynosurus*) from East Africa, a Philippine Paradoxure (*Paradoxurus philippensis*) from the Philippine Isles, three Black Tortoises (*Testudo carbonaria*) from Demerara, deposited; two Purple-faced Monkeys (*Semnopithecus leucoprymnus*) from Ceylon, a Ludio Monkey (*Cerco-*

pithecus ludio), an African Brush-tailed Porcupine (*Atherura africana*) from West Africa, three Indian Tantali (*Tantalus leucocephalus*) from India, an American Bison (*Bison americanus*) from North America, a Schomburgk's Deer (*Cervus schomburgki*) from Siam, two Side-striped Jackals (*Canis lateralis*) from West Africa, two Spotted Hyænas (*Hyæna crocuta*) from South Africa, two Crested Screamers (*Chauna chavaria*) from Buenos Ayres, five Black-necked Swans (*Cygnus nigricollis*) from Antarctic America, purchased; an Axis Deer (*Cervus axis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

Occultation of a Fixed Star by Saturn.—It is recorded by Whiston, in his life of Dr. Clarke, that the father of the latter once saw a star in the dark space between the ring and the ball, though, so far as we are aware, no date for the observation or other particulars have been preserved. Gottfried Kirch, the discoverer of the great comet of 1680, appears to have been very nearly a witness of a similar phenomenon, if indeed his telescope had been equal to the occasion. Observing Saturn at Leipsic on the evening of January 16, 1679, he remarked, about 10h., that the star *o* Tauri of Bayer (114 Tauri Fl.), of the sixth magnitude, was distant only one diameter from the extremity of the ring. The night was changeable, and clouds subsequently interfered, but two hours after midnight he found the star "quartâ forsan parte diametri Saturni, a Saturno distantem." A quarter of an hour later he saw that the distance had sensibly diminished, and in another half hour the star had become so small "adeo ut fermè conspectum fugeret. Neque procul aberat a Saturno, ut spatium inter Saturnum et stellulam, ipsius stellæ magnitudinem non superare videretur;" and he continues: "Stellula postea tangebat fermè extremum Saturni." An accompanying rough figure shows the star very nearly in contact with the extremity of the ring. Further we read: "Inter primum et secundum quadrantem post horam tertiam nihil dignoscere poteram, primo stellula Saturno adhæsisse mihi videbatur, de quo tamen nihil certi dicere possum, ipse enim dubito; deinde nihil videndum sese offerabat." But although he saw no more, Kirch states that Saturn would necessarily shortly occult the star. On the following evening, at 8h. 30m., the star was distant about a diameter of the planet, or rather, as the figure shows, of the ring. He considered from these observations that the star was in contact at 3 a.m. on January 17, and that the egress took place about 11 a.m. It will be found that Saturn did not set at Leipsic on this morning until nearly 5h. 30m., and by the track of the planet the central distance at conjunction was less than a third of the semi-diameter of the shorter axis of the ring, thus the star might be within the dark space between the ring and the globe before setting. The planet was then about 83° from the node of the ring, which must therefore have been nearly as open as we can see it. Kirch seems to have been well aware of the rarity of such an observation. It was first published in his Ephemerides for 1683.

The Polar Compression of Mars.—In November last Prof. Young made a numerous series of measures of the diameters of Mars with a filar-micrometer attached to the 9·5-inch equatorial of the School of Science Observatory at Princeton, New Jersey, U.S., the object-glass of which is stated to be of the highest excellence, having repeatedly shown both satellites of Mars, the two outer satellites of Uranus, and, it is said, the Saturnian satellite Mimas. Although measures with the wire-micrometer have been found liable to considerable constant error, it was thought they might safely be used in determining a difference of diameter. Mr. Marth's ephemeris was employed in setting the position-circle and in computing the minute corrections for phase. The total number of micrometer-readings was 1,140. The results applicable to November 12, 1879, are as follow:—

Equatorial diameter	20″·634 ± 0″·034
Polar diameter	20·552 ± 0·043
Mean	20·593 ± 0·035

These absolute values Prof. Young considered not very reliable, being subject to the considerable constant error referred to above.

Dr. Hartwig's determination of the mean diameter of Mars, by combining all the double-image measures at Königsberg, Leyden, Oxford, Berlin, Paris, and Strassburg, gives for the opposition-diameter in 1879, 19″·128, which differs from Prof. Young's result by 1″·46, which he says is a difference "rather unexpectedly large, but not unprecedented." As regards the compression, the immediate object of the Princeton measures, the final result comes out $\frac{1}{219}$, the limits of probable error extending from $\frac{1}{160}$ to $\frac{1}{382}$. The discussion of the measures was nearly finished, when Prof. J. C. Adams's paper upon the orbits of the satellites of Mars was published; he there gives $\frac{1}{219}$ as the ellipticity of the planet, if it follows the same law of central density as the earth. This near agreement is probably to a considerable extent an accidental one.

Dr. Hartwig's value for the polar diameter of Mars at distance unity is 9″·352, corresponding, with Leverrier's solar parallax, to a real diameter of 4,180 miles.

The Next Total Solar Eclipse.—At the recent annual meeting of the National Academy of Sciences at Washington, Mr. D. P. Todd, of the office of the *American Ephemeris*, communicated a paper "On the Use of the Electric Telegraph during Total Eclipses applied to the Search for Intra-Mercurial Planets," with the view to illustrate in what manner the rare moments of total eclipses may be utilised to their utmost extent, "the method consisting in the electro-telegraphic transmission of important observations made at western stations to observers at eastern stations, with due speed for their verification or rejection when the lunar shadow reaches the latter stations." Taking as an example the next total eclipse of the sun, on May 16, 1882, it is remarked that the path of totality lies almost wholly on land; commencing in Western Africa, with a north-easterly direction, it crosses Upper Egypt and the Red Sea, passing a few miles south of Bagdad and Teheran, and thence traversing Central Asia, it leaves that continent near Shanghai. Thus several widely-separated regions, connected by telegraphic cables and land lines, are upon the track of the central eclipse. Mr. Todd remarks that from El-Akhmym, on the Nile, a line runs north to Alexandria, from which place Teheran is directly accessible by telegraph. From Teheran a land-line runs south-east through Beluchistan and Hindostan to Madras, which is connected by cable-lines with Singapore, Hong-kong, and Shanghai. He points out that an additional advantage attaches to this eclipse from the circumstance that there is a duplicate line of telegraphic connection between Egypt and Shanghai by way of Constantinople, Vienna, and Moscow, and thence by the Russian line through Siberia to Wladiwostok, and thence to Shanghai. Supposing, then, that an intra-Mercurial planet were discovered during totality in Egypt, a duplicate message might be sent, to insure beyond doubt that the discovery should be known to observers at Shanghai; if a planet were observed at El-Akhmym, 45 minutes of absolute time elapsing before the shadow reaches Teheran, the position might be telegraphed to the latter station so as to give the observer abundant time to verify the discovery, while observations at both places might be telegraphed to Shanghai, which the shadow will not reach until more than two hours after leaving Teheran. Mr. Todd thinks that the telegraph companies, with the courtesy they have always shown in scientific undertakings, would render every assistance in carrying out such a scheme.

We take this outline from a report of his communication to the American Academy, received from Mr. Todd.

BIOLOGICAL NOTES

Chinese Alligators.—Two fine examples of the alligator of the Yang-tse-kiang, of the discovery of which we spoke in our issue of February 13, 1879 (vol. xix. p. 351), have recently been received by Dr. Peters for the Zoological Museum of Berlin. There can be no doubt, we understand, that M. Fauvel is quite right, and that this crocodilian is an undoubted *alligator*—being the first of this genus which has been found to occur in the Old World. It will be recollected that of the remarkable Chondrostean genus of fishes, *Polyodon*, one of the two known species is also found in the Yang-tse, while the other is confined to the Mississippi.

Fossil Corals.—The Cyathocrinidæ, as one of the largest and most ancient groups of fossils, appear to belong to a type worthy of attracting continual study. Wachsmuth and Springer (*Proc.* Acad. Nat. Sci., Philad., 1879) unite the genera Poteriocrinus and Cyathocrinus into one family, finding them agreeing in having large oral plates supporting the ambulacral grooves and covering the

ventral disk, but leaving an opening at the oral centre, which is perfectly covered by the apical dome plates. Food-grooves along the vault, closed by two rows of alternating pieces; in the presence of a porous ventral sac, located posteriorly, and closed at the top, in which the anal functions were subordinate to other offices; in having the calyx constructed of only three rings of plates alternating with each other, proximal plates sometimes imperfectly developed; no interradials. The extreme genera are very distinct, but there are intermediate forms which render it impossible to make a completely satisfactory distinction between successive genera. It is best, no doubt, to recognise (1) the earlier or embryonic types, including Heterocrinus; (2) the typical Cyathocrinidæ, (3) the Poteriocrinus type, (4) the Teacrinus type, including Woodocrinus, (5) and transitional forms towards Encrinus, such as *Eupachycrinus*. Little difficulty is found in referring all Cyathocrinidæ from the upper Silurian to the close of the carboniferous to one of the groups Poteriocrinus or Cyathocrinus, although the anal plates vary much in form. In the lower Silurian members of the family this is more difficult, yet careful study gives rise to the idea that the later were probably developed from the earlier Silurian types.

Circulation in Worms.—The existence of a double circulatory apparatus in a certain number of types belonging to the class of worms has been known; it consists of a closed vascular apparatus containing a red blood without corpuscles, and of the connected lacunæ of the body (not properly a distinct organic apparatus), containing colourless blood with white corpuscles. From a sealed packet lately opened in the Belgian Academy it appears that M. van Beneden had discovered in 1871 a double apparatus and two sanguineous liquids in the lower Arthropoda; this is found in the genera *Clavella*, *Congericola*, and *Lernanthropus*. The vascular apparatus with red blood and contractile walls, very simple in the two former, becomes very complex in *Lernanthropus*. The foliaceous lamellæ fixed to the posterior part of the body are true branchiæ, organised exactly like those of annelids. There is no central organ of circulation; the circulation of the two liquids is caused by contractions of the body. In *Lernanthropus* the branchiæ, abdomen, and cephalothorax contract and spread alternately.

Large Cuttle Fish.—All exact information about gigantic Cephalopoda is of interest not only as showing what immense marine creatures do exist, but as preparing us for the possibility of meeting with still greater. Prof. Verrill has collected a great deal of accurate and recent information as to the North American species, of which he publishes a list in the April number of the *American Journal of Science*, from which we cull the following:—On November 2, 1878, a fisherman was out in a boat with two other men near Leith Bay Copper Mine, Notre Dame Bay, when they observed some bulky object not far from shore, which they approached, thinking it might be part of a wreck. To their horror they found themselves close to a large fish having big glassy eyes. It was making desperate efforts to escape, and was churning the water into foam by the motion of its immense arms and tail. Finding it partially disabled, they plucked up courage and threw the boat's grapnel, which sank into its soft body. By means of the stout rope attached to the grapnel and tied to a tree the fish was prevented going out with the tide; its struggles were terrific as, in a dying agony, it flung its great arms about. At length it became exhausted, and as the water receded it expired. Its body, from the beak of the mouth to the extremity of the tail, measured twenty feet, and one of the tentacles, or arms, measured thirty-five feet. This is the largest specimen yet measured of *Architeuthis princeps*. Prof. Verrill mentions eighteen species as now known on the north-eastern coast of America.

Sternum in Dinosaurs.—Prof. O. C. Marsh describes, in the *American Journal of Science* for May, 1880, the sternum in *Brontosaurus excelsus*. The Yale Museum has recently received a nearly complete skeleton of this, one of the largest known Dinosaurs. This huge skeleton lay nearly in the position in which the bones would naturally fall after death, and fortunately the entire scapular arch was in excellent preservation. The coracoids were in apposition with their respective scapulæ on each side, and between them lay *two* flat bones that clearly belong to the sternum. This discovery, as interesting as it was unexpected, removes the main uncertainty about the scapular arch of Dinosaurs, and likewise indicates a new stage in the development of this structure, not before seen in adult animals. These two sternal bones are suboval in outline, concave above and convex below. They are parial, and in position nearly or quite joined each other on the median line. The anterior end of each bone is considerably thickened, and there is a distinct facet for union with the coracoid. The posterior end is thin and irregular. The inner anterior margin of each bone is smooth and rounded, and gives no evidence of union with an episternal element, which the vacancy there suggests. The amount of cartilage between these two sternal bones or posterior to them is not indicated by the present specimens. They were evidently separated by cartilage from the coracoids. The nearest analogy among living forms to this double sternum may perhaps be found in immature birds. A close resemblance is apparent in the scapular arch of the young American ostrich. If the ossification of the sternum were permanently arrested at this stage it would afford almost precisely the structure seen in the genus *Brontosaurus*; and this is evidently the true explanation of the fossil specimens. It is more than probable that in many Dinosaurs the sternum long remained cartilaginous, or so imperfectly solidified that it is not usually preserved. Several specimens of the genus *Camptonotus*, found nearly in their natural position, were apparently destitute of an ossified sternum. The large size, and doubtless great age, of the specimen of *Brontosaurus* above mentioned may perhaps have been the cause of its more perfectly developed sternum.

Antipatharia of the "Blake" Expedition.—In vol. iv. No. 4 of the *Bulletin* of the Museum of Comparative Zoology at Harvard College, Cambridge, Mass. (February), L. F. Pourtales describes twelve species of this interesting group taken in the Caribbean Sea (1878-79). In determining the species an attempt has been made to use the differences in the shape of the polyps, as well as the disposition and form of the spines to draw characters for a much-needed revision of their classification. It would seem as if there were at least two different types of spines: the triangular compressed and the more cylindrical. These latter are generally more densely set, even assuming sometimes a brush-like appearance, as in *Antipathes humilis*, a new and wonderfully spinous species, figured but not described by Pourtales. These cylindrical spines are also unequal on the two sides of the pinnules, being longer on the side occupied by the polyps, with a few very much longer around the polyps. The triangular spines are disposed regularly in a quincuncial order around the pinnules, and in a cleaned specimen nothing indicates the place formerly occupied by the polyps. In one species, however, *A. desbonni*, the spines are in regular verticils. There would appear to be a connection between the shape of the polyps and the shape and disposition of the spines. Those species with triangular spines have polyps with longer tentacles than those with cylindrical spines, and the tentacles have a greater tendency to become regular in shape. In many species the tentacles are simply contracted; in a very few they were found retracted, as figured by Lacaze-Duthiers; and in some they are probably not retractile at all. Eight out of the twelve named are either described or figured as new species. *A. spiralis* is a very interesting species, formerly referred to *A. desbonni*, D. and.M. The polyps are alternately large and small, with very large digitiform tentacles, much longer than have been figured of any antipathes before. In the spaces between successive polyps the cænosarc shows transverse canals, and those on the back part of the branch are more transparent than the rest.

American (East Coast) Siphonophora.—In the March and April *Bulletin* of the Museum of Comparative Zoology at Harvard College, Cambridge, Mass. (vol. vi. 5-7), Mr. J. Walter Fewkes gives a sketch of the development of the tentacular knob of *Physophora hydrostatica*; he describes the mantle-tubes of *Apolemia uvaria* and *Gleba hippopus*, the tubes in the larger necto-calyx of *Abyla pentagona*; he adds some critical remarks on the genera Halistemma, Agalma, and Agalmopsis, and he concludes with a notice of the forms of Siphonophora and Velellidæ, to be met with on the eastern coast of the United States. Up to the present few forms of either of these groups have been described from American waters. They seem to be only occasional visitors blown into the neighbourhood from mid-ocean, and brought there from the tropics by the Gulf Stream. The wealth of such species that one meets with in the Mediterranean is unknown on the New England coast; while, as the author says, in one day at Nice he has taken eight different genera of Siphonophoræ, yet at Newport he has but rarely taken as many as two genera in the length of a summer's day, and a whole summer once passed, during most of which he was almost daily on the water without one species being seen. One

or two species of Physalia are, however, more common on the United States coasts than in the Mediterranean. The only member of the long-stemmed Siphonophoræ provided with a float or air-bladder found heretofore on the New England waters is *Agalmopsis cara*. Mr. Fewkes can now add *A. elegans*, and he thinks that extended observation in the southern bays of the country will bring to light some of the well known forms common to all oceans, such as Apolemia, Abyla, Physophora, and Gleba. Some of these have already been taken in the Gulf of Mexico and the Caribbean Sea. Rhizophysa, found in the same localities, might also be expected to be brought to the Eastern American coasts by oceanic currents.

PARASITE ON THE AMERICAN BLUE PIKE.—In the *American Journal of Microscopy* for March, Prof. D. S. Kellicott describes a new species of Argulus found on the blue pike (*Stizostethium salmoneum*, Jord.). The fishermen of the Niagara River at Buffalo say that when the water becomes warm the fish gets too lazy to take food, that it then loses flesh, and through its inertness becomes infested with these lice. Having given this subject especial attention, Prof. Kellicott is inclined to think the account of the fishermen is correct. The parasite occurs usually on the top of the head of the fish. When there are several they are, as a rule, huddled together often in heaps, so that the knife may remove a number at once; it occurs also on the fins. None were found in the mouth cavity. As many as twenty were taken from one lean fish. When living specimens of the Argulus were placed in a tank with a small specimen of *Lepidosteus osseus* and some minnows, they shortly fixed on them, and the minnows soon died, apparently killed by the parasites. When first put in, the fish would pursue and catch them, but would eject them with a suddenness and a queer expression that was most amusing. In a few moments they were left unnoticed by the minnows. The gar recoiled in evident fear when one would be seen approaching. A large female once fastened on to the end of the long nose of the gar, where it clung for several days, despite the vigorous efforts of the fish to dislodge it. Cold weather seemed to destroy them: the fishermen assert that after frosts the blue pike become fat, and then no lice are found on them. The species is called *A. stizostethii*. The author believes—against the assertion of Leydig—that the abdominal lobes have a function of respiration above all other parts of the body, and he describes with a good deal of detail the appendages to the several legs.

MOTION IN ALGÆ.—From some interesting observations recently made by Herr Stahl, as to the influence of light on the motions of algæ (*Verhandl. der phys.-medic. Gesellsch. in Würzburg*, Bd. xiv.) it appears that light has a directive influence on *Closterium moniliferum*, the cell of which tends to place its longitudinal axis in the direction of the light rays, and a certain opposition appears in the two halves of the cell, such that one half is attracted to the light and the other half repelled. Further observation showed that the closteria underwent periodic changes, in virtue of which the two halves alternately at successive intervals turned towards the light. These experiments were made with diffuse daylight of little intensity. When the intensity of the light was increased, the orientation of the closteria was changed; the position parallel to the light rays was given up, and the cells placed themselves at right angles to the incident light. This cross position could be again exchanged for the parallel one by deadening the light. Whether temperature has much to do with these positions of closteria has not yet been determined; the temperature of the minimum seems to be not without action on the period between two reversals. The foregoing experiments should be made with quite healthy vigorous closteria. Some other phenomena of orientation were observed by Herr Stahl in *Micrasterias rotata* and in a species of *Mesocarpus*.

GEOGRAPHICAL NOTES

THE fiftieth anniversary meeting of the Geographical Society was held on Monday afternoon, the Earl of Northbrook presiding. Apart from the flourishing condition of the Society, both numerically and financially, the most interesting feature in the Council's Report was the part relating to the annual grant for scientific purposes. During the past year a plan was put into operation for giving practical instruction to intending travellers in the use of instruments for astronomical observations to fix positions, in surveying, and in the measurement of heights by barometric and hypsometrical methods. This attempt to improve the scientific training of our travellers has already met with considerable success, and several of the pupils who have received instruction have left for China, Afghanistan, Central Africa, Central Asia, &c. In order to facilitate the instruction in astronomical work, an observatory has been built on the roof of the Society's house. The medals and other awards were afterwards distributed by the President, Count Piper, the Swedish Minister, receiving for Prof. Nordenskjöld a copy of a special vote of thanks and his diploma as Honorary Corresponding Member, as well as the royal medal for Lieut. Palander. Mr. W. Giles received the other royal medal for his cousin, Mr. Ernest Giles, and Mr. R. N. Cust the gold watch awarded to Bishop Crowther for his services on the Niger. A copy of a resolution of the Council, eulogistic of his "History of Ancient Geography," was also read and handed to Mr. E. H. Bunbury. The gold and silver medals having been given to the successful candidates in the recent public schools prize examination, the ballot was taken for the new council, resulting in the election of Lord Aberdare as President, and Mr. John Ball, F.R.S., Sir Fowell Buxton, Mr. J. K. Laughton, Sir George Nares, Lord Reay, and Sir Richard Temple, in the place of the retiring members of council. In the course of his annual address Lord Northbrook summed up the results of recent explorations in the Arctic regions, in Asia, and in Africa, as well as of Admiralty surveys in various parts of the world.

HERR VON BOGUSLAWSKI publishes, in the *Annalen der Hydrographie*, the conclusions to which he has been led by recent observations on ocean temperatures:—1. The waters of the North Pacific are in general colder than those of the North Atlantic. 2. The waters of the South Pacific are warmer than those of the South Atlantic, to a depth of 1,300 metres; beyond that they are colder. 3. The bottom temperatures are generally lower in the Pacific than in the Atlantic at an equal depth and in the same degree of latitude; but we do not find any part of the temperature in the former as low as those of the Antarctic part of the South Atlantic between 36° and 38° S. lat. and 48° and 30° W. long., where in seven places temperatures of $-0°\cdot3$ to $-0°\cdot6$ were found. 4. In the west part of the Pacific and in the neighbourhood of the Indian Archipelago, the temperature of the water reaches its minimum at depths which vary from 550 to 2,750 metres, and remains the same from that depth downwards. In all the Atlantic the temperature from 2,750 metres lowers slowly but regularly.

THE Council of the German African Society has now arranged with the King of Belgium, as president of the International African Association, that, instead of carrying out their former intention of establishing a German station on the southern bank of Lake Tanganyika, their expedition, which is now at Zanzibar, preparing for their tour into the interior, shall first establish a station at Mangasa; that, however, the right to found a second station near Lake Tanganyika shall be reserved to them. Dr. Pogge of Mecklenburg, already well known through his African travels, will become the director of this second station, which will now perhaps be established at Mussumba, the capital of Muata Tamwo. This station will form a link in a complete chain of small settlements which are to extend all over the Dark Continent.

A LETTER in the *Deutsche Zeitung* announces that, after five months of unremitting toil, the Austrian African traveller Marno has been able to break through the obstacles on the White Nile caused by the unchecked growth of twenty months, and has re-opened the navigation for trade and passenger traffic. Accompanied by the photographer Buchta, also an Austrian subject, Marno had made a trial trip on a small steamer belonging to the Egyptian Government, penetrating as far as Ladova, and returning safely.

A LIST of 25,000 geographical terms in most frequent use has been drawn up in Chinese by Li Fêngpao, Chinese Minister at Berlin, with the assistance of Dr. Kreyer and Dr. Allen. This list is the basis upon which a large atlas of the world on Mercator's projection has been prepared and photolithographed at Berlin. It also represents the nomenclature employed by Dr. Kreyer in a translation of Daniel's Geography, a large standard work in sixteen Chinese volumes.

WE regret to learn that Père Horner, who has been a true friend to many an African explorer, died at Bordeaux on May 20. He had but recently returned from Zanzibar, where he had resided for many years, and had taken an active interest in all attempts to put down the slave-trade in Eastern Africa, and in

this connection we believe that he rendered valuable service to Sir Bartle Frere during his mission to Zanzibar.

THE *New York Herald* of May 14 says:—The evidences multiply which go to show that there has been an early and exceptionally large break-up of the ice-fields within the Arctic basin since the sun crossed the Equator. The extraordinary mildness of the last winter was universally marked east of the Rocky Mountains, and it would seem the abnormally high temperature extended far to the north and made its impression on the icy seas. Off the coast of Newfoundland the recently reported ice drift will be memorable not only for the magnitude, but also for the multitude of the icebergs and the ice-fields. On the western side of the continent the winter reports indicated a milder season in the vicinity of Behring Sea and its Polar approaches. It is not improbable, therefore, that the steamer *Corwin*, about to sail for the relief of the missing whalers and to communicate with the American Arctic expedition in the *Jeannette*, will find that the premature development of the spring has already loosened their icy bonds, and that they are preparing to pursue their respective routes. The sun's power may be insufficient to dissolve the *Jeannette's* solid moorings, but the mightier agency of winds and waves attending the storms that sweep the ocean north of Behring Strait in May and early June may be expected to break up the ice off Wrangell Island and accomplish her release sooner than if she had wintered on the north-east side of Arctic America.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Prof. Humphry's Rede Lecture on man was interesting and eloquent, if on the whole rather depressing. He pleaded for long and patient investigation, especially in coming to the discovery or comprehension of any process, whether of natural selection or any other, by which the large cranial cavity of man can have been evolved in early men. He gave full weight to the argument from the size of the brain at birth, and the perfection of the lungs at the same period. At any rate the brain of primitive man appeared to have been structurally fitted for higher duties than they were ever called upon to perform. His brain was prophetic of his future. Ability is to be measured by the power to deal with the material before us; and thus it is doubtful whether the ability of the present was greater than that of preceding generations, prehistoric or historic. Progress did not necessarily imply improvement, and increased means did not imply greater power, however they might enable power to be wielded with better effect. The physical capability, he thought, long preceded functional activity; and man's advance to civilisation was the result of the response of his nature to his conditions. He believed in the great value of contact and blending of varieties, and attributed the stationary condition of certain races partly to their early progress keeping them exclusive, and to the physical conditions which had walled them in. The climate of the temperate portions of the Eurasian Continent proved favourable to the development of the energies of mammals and men, and the configuration of the northern continent was especially favourable to migration. Thus there had nowhere been through any long period the still dulness of pure blood or the cramping domination of one power. The mingling of races in Britain, in a land of great natural advantages and resources, had led to the development of ability in the people to work out freedom, to invent, to adopt international conventions, and to free others. But he perceived dangers in the increased sensitiveness accompanying the great subdivision of labour nowadays. Of the two evils, learned feebleness was a greater evil than ignorant strength. The preservation of the weak and sick did not make the mass of people stronger and healthier; thus there must be sterner sanitary precautions as a foremost question. Would that some of the time spent on Burials Bills could have been spent in considering the crying needs of the health of the living. This misapplication of energy, said the Professor, had its parallel in the mistaken efforts to prevent the investigations by which physiology might be advanced and the laws of health educed. Few things would tend to the improvement of the race so much as judicious matrimonial selection, and he hinted at the importance of providing a healthy race for the future. Finally, as to man's body at least, and its future, he felt compelled to say that we found ourselves floating on the stream of time; the barque, we suppose, moves on. Sufficient for the day must be the knowledge thereof. Whether we peer fore or aft, it is obscurity.

SIR GEORGE JESSEL, the Master of the Rolls, has been elected Vice-Chancellor of London University, in place of Sir John Lubbock, who resigned on his becoming a candidate for the representation of the University in Parliament. The election is not likely to be contested.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, May 24. Anniversary Meeting.—Prof. Allman, F.R.S., president, in the chair.—At this, the ninety-second annual general meeting, there was a large attendance of the Fellows. The President, after a few introductory remarks of congratulation on the prospects of the Society generally, referred to the obituary, pointing out that several of the oldest members would now no longer appear on the list. Among others, Prof. T. Bell (*æt.* 87), J. Miers (*æt.* 91), Gen. Munro, Dr. David Moore, Wilson Sanders, E. W. Cooke, R.A., Fellows, and T. Atthey, Associate, besides Foreign Members of high standing, showed a heavy death-roll. The Secretaries and Treasurer, after full term of service, had proposed to resign, and as a matter of form this had been acceded to by the Council. The Secretary (Mr. F. Currey) then read his report. Since the last anniversary the Society had lost by death ten Fellows, three Foreign Members, and one Associate; and three Fellows had withdrawn. On the other hand, there had been an accession by election of twenty-eight new Fellows, three Foreign Members, and four Associates. The library showed a marked increase and improvement, by additions obtained by purchase, exchange, and donations, and had been amply used in biological reference and loan of books. The scientific communications and exhibitions at the meetings during the session had kept pace with the march of science, and the attendance of the Fellows bore witness to the active interest taken in the proceedings generally. —The Treasurer (Dr. J. Gwyn Jeffreys) then read his report. In resigning office he congratulated the Society on its increasing prosperity in a financial point of view. Notwithstanding the late depression of commerce, which had to a greater or less extent injuriously affected other scientific societies, as well as the additional yearly expenditure consequent on the removal to Burlington House, and the greater amount of salaries paid, the publications had not been restricted; considerably more having been spent on the library than formerly. The Society is quite free from debt; has an invested capital of £3730 12*s.* 8*d.*, and the balance at bankers and on hand at this date is £522 18*s.* 2*d.* Twelve months ago, owing to the unfortunate and long illness of the Librarian, his accounts became confused, and the Asst.-Secretary had since undertaken the receipts and payments, and had the books thoroughly balanced. A Special Committee had also been appointed by the Council for investigating the financial position of the Society, and their valuable suggestions had been adopted, especially as to the reasonable limitation of the publication expenses, which had increased from £796 14*s.* in 1876 to £1100 5*s.* 1*d.* in 1879. With respect to the compositions, which, even if they were altogether invested, must seriously diminish the income of the Society, the Treasurer stated that during his five years of office he had received £1968, and invested £920 15*s.* During the previous five years no part of the compositions appear to have been invested. He had also received and invested £840 for legacies. The Society's capital had been doubled; it was in 1875 £1860, and is now £3730 12*s.* 8*d.* The annual contributions received in 1876 amounted to £694 13*s.*, and last year to £948 12*s.* The ballot for Council and Officers having been proceeded with, the following gentlemen retired from the Council:—Messrs. J. Ball, W. Carruthers, F. DuCane Godman, Dr. A. Günther, and the Rev. G. Henslow. In their places were elected:—Messrs. E. R. Alston, G. Bentham, G. Busk, Dr. M. Foster, and B. D. Jackson. For the Officers, Prof. G. J. Allman was re-elected President; Mr. Fredk. Currey (the outgoing Secretary), Treasurer; Mr. B. Daydon Jackson, Botanical Secretary; and Mr. Edward R. Alston, Zoological Secretary.—Prof. Allman thereafter gave his usual annual address, taking for his subject "The Vegetation of the Riviera, a Chapter in the Physiognomy and Distribution of Plants." In this address (not well adapted for brief abstract), by a few broad outlines, a sketch of the most striking features of the vegetation and its peculiarities as derived from the physical contour of the country, geographical position, and climate, was given. The phenomena extant are of high interest

to the botanist, for though belonging to the European area, the Riviera exhibits in climate and character of vegetation an obvious link between the temperate and tropical zones. Its accessibility and singular flora, with scenes of unrivalled beauty, offer ample material for study.

Statistical Society, May 11.—Dr. W. A. Guy, F.R.S., in the chair.—Two papers were read: the first by Capt. P. G. Craigie, Secretary of the Central Chamber of Agriculture, on ten years' statistics of British agriculture, 1870-79, and the second by Messrs. J. B. Lawes and J. H. Gilbert, on the home produce, imports, consumption, and price of wheat, over twenty-eight harvest years, 1852-53, to 1879-80, inclusive. Messrs. Lawes and Gilbert in their paper arrived at the following conclusions:—The area under wheat was about 20 per cent. less over the last three than over the first eight years of the twenty-seven. The average produce per acre over the United Kingdom amounted to only $27\frac{5}{8}$ bushels over the whole twenty-seven years as compared with $28\frac{3}{4}$ bushels which we had previously assumed to represent the average produce per acre of the country at large. The annual imports averaged about three times as much over the last three as over the first eight of the twenty-seven years. The total consumption of wheat per annum had increased from an average of about 18 million quarters over the first eight years to nearly 24 million quarters over the last three years. The price of wheat per quarter had declined from an average of 57*s*. 8*d*. over the first eight years (including the period of the Crimean war) to 49*s*. over the last three years. The annual value of the home produce available for consumption had declined from an average of nearly 38,000,000*l*. over the first eight years, to less than 25,000,000*l*. over the last three years. The annual value of the imported wheat had increased from an average of little more than 13,000,000*l*. over the first eight years, to more than 33,000,000*l*. over the last three years. Over the whole period of twenty-seven years, 40·4 per cent. of the wheat consumed had been derived from imports; and the amount supplied from foreign sources had increased from an average of 26·5 per cent. of the total over the first eight years, to 57·4 per cent. of the total consumed over the last three years of the twenty-seven.

January 27.—Carcinological notes: Revision of the Gelasini, by J. S. Kingsley.—On the Pacific species of *Caulolatilus*, by W. N. Lockington.

PARIS

Academy of Sciences, May 24.—M. Edm. Becquerel in the chair.—The following papers were read:—On the secular variations of the mathematical figure of the earth, by M. Faye. Regarding the anomaly of the small action of such masses as the Himalayas on the pendulum, and the great attractive force often found at sea, he points out that under seas the cooling of the globe proceeds more quickly and deeply than under continents. The bottom of the first seas would thicken in advance of the dry crust, and would press increasingly on the liquid nucleus, raising the weak parts of the first crust, which were mostly round the North Pole. The water level would rise on our hemisphere and fall on the southern, and the ellipsoid of revolution become a simple spheroid. With further cooling the basins of the southern seas would have increasing attraction and the waters would gradually rise in the southern hemisphere, their surface of level returning to the ellipsoidal form, which, M. Faye thinks, is slightly exceeded at present. Thus the earth's crust shows an alternate balancing movement determined by excess of weight of maritime crusts and the points of less resistance in the heart of continents.—On the refrigerating mixtures formed by an acid and a hydrated salt, by M. Berthelot. The chemical energies act according to the principle of maximum work, giving a first exothermic reaction; then the calorific energies act inversely, causing absorption of heat under the four-fold form of dissociation, disaggregation by the solvent, dissolution, and liquefaction.—Action of acids on alloys of rhodium with lead and zinc, by M. Debray. He describes a peculiar substance (deflagrating at about 400° with heat and light) obtained from treating the rhodium-lead alloy with nitric acid. Rhodium forms, with zinc, alloys which may exist in two isomeric states, giving very different reactions.—Determination of the position of a bridge to be constructed over the Danube, near Silistria, by M. Lalanne.—On the transcendants which play a fundamental part in the theory of planetary perturbations, by M. Callandreau.—On the theory of ideal complex numbers, by M. Dedekind.—Integration of certain differential equations with the aid of functions Θ, by M. Appell.—On elimination, by M. Le Paige.—Industrial utilisation of solar heat, by M. Mouchot. He has been experimenting near Algiers since May last year. He specifies improvements, (*e.g.*, an arrangement for keeping the liquid to be vaporised in contact with the whole heated surface), and indicates results. *Inter alia*, since March the receiver has actuated a horizontal engine (without expansion or condensation) at the rate of 120 revolutions a minute with constant pressure of 3·5 atm.; the disposable work being about 8 kgm. he set it to work a pump giving 6 litres per minute at 3·50m., or 1,200 litres per hour at 1 m., and to throw a jet 12 m. This goes on from 8 a.m. to 4 p.m.—Combinations of alcohols with baryta and lime; products of decomposition, by heat, of these combinations, by M. Destrem.—Reactions produced between ammoniacal salts and carbonate of lime, by M. Nivet. A double decomposition is shown to occur in the ground and in water, the result being a loss of ammonia, which is greater, the less absorbent the soil, or the less the quantities of CO_2 formed in it.—On the formation of callosity, by MM. Rigal and Vignal.—Experiments relative to peritoneal shock, by MM. Reynier and Richet.—On the form and the seat of movements produced by cortical excitation of the brain, by M. Couty. There is no relation between the cortical region excited and the form or the place of the motions. Explanation of the phenomena is possible only by admission of the theory that the cortical white fibres are conductors of bulbo-medullary excitations, and comparable to the peripheric conductors, notwithstanding their course and their much more complicated connections.—On the fixing power of certain organs for alkaloids introduced into the blood which traverses them, by M. Héger. The hepatic tissue retains most; the lungs absorb very little.—Discovery of horse-pox vaccination, by M. De Pietra-Santa. Several heifers were successively (and with effect) inoculated in Paris with lymph from a young blood horse which had come from Germany, and had horse-pox.—On a phenomenon of sensibility observed in acacia, by Mr. Phipson. He obtained this by striking the terminal leaflet several times with his finger.—On the tertiary strata of Brittany; environs of Saffré (Loire-Inférieure), by M. Vasseur.—M. Dubrunfaut returned several pieces (letters, memoirs, and reports) belonging to the Archives of the Academy.

"OLD NORWAY"

Die Geologie des südlichen und mittleren Norwegen. Herausgegeben von Dr. Theodor Kjerulf; autorisirte deutsche Aufgabe von Dr. Adolf Gurlt. (Bonn: Max Cohen und Sohn, 1880.)

IN that rugged northern land where the mingled Atlantic and Arctic tides course round a network of islands, and lave the shores of deep lonely fjords, sending their waters far inland to the very base of snowfield and glacier, the people, with the patriotism of mountaineers, sing enthusiastically of "Gamle Norge"—Old Norway. And well may they sing of a land that by its scenery and climate has moulded their habits of thought, their traditions, their literature, and has knit their bodily frames into that muscular type for which the hardy Norsemen have been famous from time immemorial. Dear Gamle Norge! The sound of its praise awakens a responsive chord in the breast of many a Briton, leading him to reflect how much of the vigour and success of his own countrymen may be due to the fresh blood which came to them from the robust north, and reminding him of the wild creed and spirit-stirring songs which his ancestors shared with their kinsmen of the northern fjords. Well may men speak of "old" Norway. Even as regards human records, its antiquity goes back far enough to merit that appellation. But if we pass to the earlier history of Europe the fitness of the epithet becomes singularly impressive. To that northern region of tableland and valley the geologist looks as the cradle of this continent. The plains of Russia and Germany are formations but of yesterday. The Urals, the Alps, the Pyrenees, the high grounds of Bohemia, Saxony, and Central France have appeared at various widely separated epochs, and have undergone many vicissitudes in a long course of ages. But the uplands of Scandinavia, though they too have not been without their mutations, already existed as land almost at the beginning of those ages which are chronicled in the rocky records of the earth's crust. From the sand and mud washed down from these uplands the formations have been derived out of which, for example, most of the highlands of Scotland, Wales, and Ireland have been built up. So far as we can tell, the earliest land of Europe rose in the north and north-west. The subsequent growth of the continent has been over the tract of shallow sea by which the first land was bounded.

There is thus a peculiar interest in the study of the geological structure and history of Scandinavia. It is in that region that by far the largest fragment of archæan Europe exists and that the data are chiefly to be sought from which the earliest chapters of European geological history must be written. Most cordially, therefore, will all geologists welcome the volume which Dr. Kjerulf has just published for their information. It is by much the most important summary of Norwegian geology which has yet appeared.

In an interesting preface a sketch is given of the progress of geological inquiry in Norway. After numerous private and unconnected researches by natives and foreigners in different parts of the country, a systematic geological survey of the country was in 1858 projected by Dr. Kjerulf and Bergmeister Tellef Dahll, and on the approval of the plan by the Norwegian Government, was commenced at the national expense. Its main object was to make a geological map of the country with the requisite sections. The Survey was organised very economically under Kjerulf and Dahll, with no special office, no place to store specimens, no laboratory, and no official channel of publication for its memoirs. With praiseworthy enthusiasm the two geologists continued for ten years to work in the field during the brief Norwegian summers, either together or singly, taking with them as volunteer assistants such students of mining and others as chose to accompany them. In 1866 Dahll undertook the investigation of Northern Norway, so that the charge of the Central and Southern provinces then fell to Kjerulf. The latter geologist, with the assistance of other observers, whose share in the work is duly chronicled, has at intervals published maps and sections of the area under his control, and in particular a general map on the scale of one-millionth. As a fit conclusion to the labours of a quarter of a century among the geological formations of Norway, he has published at Christiania a quarto volume with an atlas of plates, giving a concise account of the geological features of the central and southern part of the country.[1] This work is in Norse; but the author, with the view of making it more widely known, has intrusted it to Dr. Gurlt, who has rendered it successfully into German, and has had it republished in a convenient form.

Every student of metamorphism and the crystalline schists must procure Dr. Kjerulf's work. It contains a store of facts of the utmost importance for all theoretical questions in this most interesting and difficult department of geology. At the same time the superficial geology is not neglected. The first part of the volume treats of the loose surface formations—especially of the erratic blocks, moraines, and glacial striæ. These phenomena are illustrated by maps, on one of which—that of the striated rock-surfaces—an explanatory remark affords a characteristic sample of the author's cautious spirit of observation:—"The directions of the striæ are expressed on the map, as in nature, by lines; the observer must himself judge whence they come and whither they go." The second part, devoted to a summary of the geology of the Christiania district, contains a table of fossiliferous deposits, which, extending from the base of the Primordial zone to the top of the Upper Silurian formations, are shown to attain there a thickness of 2,700 feet. There is likewise an important tabular statement of the horizons of the leading organic remains of these older palæozoic deposits. In Part III. a description is given of the "Grundgebirge," or fundamental rocks of Southern Norway. The author shows that though these have sometimes been classed under the general term gneiss, they contain other rocks, especially various schists, quartzites, conglomerates, and limestones, and that gneiss is rather a structure belonging to rocks of different ages than a formation of one geological date. He regards the bottom gneiss as a metamorphic representative of ordinary sedimentary formations, in

[1] "Udsigt over det Sydlige Norges Geologi" (Christiania, 1879).

particular of the so-called "Sparagmite" or fragmental accumulations below the Primordial zone. He believes that the older gneiss may include metamorphosed portions of younger formations, in particular considerable masses of the Primordial rocks. This question in another form is discussed in Part IV., which treats of the geology of Central Norway. To the oldest sedimentary formations, termed the Sparagmite series, a thickness of 2,300 Norwegian feet is there assigned. They consist of sandstones, conglomerates, schists, slates, and limestones. Above them lie the Primordial beds, 2,900 feet thick, composed of quartz-schists, mica-schists, "blue-quartz," sandstones, clay-slates, and limestones, among which are found the earliest fossils (*Dictyonema*, *Olenellus*, &c.). Above these rocks the unfossiliferous red sandstones and conglomerates of the west coast (? Old Red Sandstone), long since described by Naumann, close the geological record until the deposits of the Glacial period. Dr. Kjerulf brings forward many facts regarding the metamorphism of the older palæozoic rocks in Central Norway, and traces with clearness the passage of these rocks into schistose and gneissose masses as they approach the larger areas of granite. Part V. is devoted to a brief exposition of the geology of the Trondhjem district. Part VI. discusses the lithology of the eruptive rocks. The various species and varieties of granite, syenite, porphyry, gabbro, greenstone, olivine-rocks, &c., are here described with remarkable succinctness alike as to their composition and geological relations. Considering the meagreness of the official equipment of the Geological Survey, this portion of their work must be admitted to be specially creditable to the Norwegian geologists. In Parts VII. and VIII. information is given regarding the structure of rocks and mineral veins. Some nature-printed illustrations of rock-structure here inserted are interesting. Slices of foliated, graphic, and porphyritic granite, etched with hydrofluoric acid, have allowed the more durable quartz to print its figure upon paper, and the impression has then been photographed on wood and cut into a woodcut. Some figures are also added to show the coexistence of organic remains (graptolites, corals) with crystals of chiastolite, vesuvianite, and other minerals in metamorphosed Silurian rocks.

A useful feature in the German translation is the addition of an index, which is wanting in the original, but which would have been still more acceptable had it been even fuller than it is. The numerous woodcut sections enable a reader to follow the local descriptions in the text. But the addition of a good geological index-map, such as that which accompanies the Norwegian volume, would have been of much service, and might perhaps have been given without any very serious increase of price. But this is a defect which every geological reader, at a little cost to himself, can remedy by obtaining the general map. He will find in Dr. Gurlt's version of Dr. Kjerulf's memoir an invaluable compendium of Norwegian geology, and will probably be induced to set out himself to make a personal exploration of the sections which are therein described. Should he be induced so to do he will doubtless come to look back on his tour in Norway as one of the most instructive as well as delightful of all his geological rambles.

ARCH. GEIKIE

EUCALYPTOGRAPHIA

Eucalyptographia; being a Descriptive Atlas of the Eucalypts of Australia and the Adjoining Islands. By Baron F. von Mueller, K.C.M.G., M. and Ph.D., F.R.S., Government Botanist for the Colony of Victoria. Decades 1 and 2. (Melbourne and London, 1879.)

MATERIAL for the issue of this atlas was accumulated at Melbourne now over thirty years ago, and the study of this fine group of the myrtles has been carried on ever since, as opportunities presented themselves by Dr. Mueller. Still the subject was so large and the perplexities surrounding it so many that even now he offers his observations in these decades as only fragments toward a some day complete monograph. The difficulties surrounding the study of this group are many. There is the large number of species, the genus Eucalyptus being surpassed in this respect only by Acacia. The resemblance of many specific forms is apt to deceive one; the fruits, and more especially the flowers, are often far out of the reach of the ordinary traveller, even though he might in his enthusiasm not object to climb for a considerable height into the trees; and then the species themselves are widely distributed over the whole of the Australian continent and Tasmania, some even extending to the Indian Ocean Islands, though, it may be added, none occur in New Zealand.

Mr. Bentham's grouping of the species has been, with some trifling modifications, adopted by the author, and the Government of West Australia has borne the expense of issuing these two decades, which contain descriptions of some of the most important timber trees of the great western colony. It is to be hoped that some of the other colonial governments may follow this good example, and so help on the publication of the work. Perhaps even our own Royal Society might see their way to help it by a grant in aid out of the fund placed at their disposal by Parliament for promoting scientific research.

The economic value of these eucalypts needs scarcely to be insisted on. Not only do they yield excellent hard timber, but as products we find enumerated oils, tars, acids, dyes, tan, and potash. What magnificent forest trees are to be found among them will appear from the description of some of the species figured in these parts. One (*E. goniocalyx*) is mentioned as growing on low or hilly woodlands up to about 3,000 feet, and attaining in some of the forest valleys a height of 300 feet, with a stem diameter of not rarely six feet, and sometimes even ten. The timber of this species is described as hard and tough, exceedingly durable, lasting well when buried underground, not warping, and difficult to split. Another species (*E. leucoxylon*) known as the iron bark tree, or white gum tree, grows to a height of 200 feet, has a timber of great hardness, durability, and of extraordinary strength. On being burnt for charcoal it yielded 28 per cent. of superior stuff, 45 per cent. of crude pyroligneous acid, and 6 per cent. of tar. An excellent packing paper has been prepared from the inner layers of the bark, as can indeed be done from the inner bark of most eucalypts, and the leaves yield a volatile oil to the extent of about 1 per cent.

The genus thus abounding in useful products is not

wanting either in remarkable forms; thus *E. alpina* is found only on the summit of Mount William, Victoria, at an elevation of over 4,000 feet, and its area is limited to the top of this one peak, for it does not even extend to any of the other summits of the chain of which Mount William is the culminating point. This species has been cultivated in the Melbourne Gardens from seeds collected in 1853, but even in good soil it retains a dwarf bushy habit, having in a quarter of a century not grown over a dozen feet in height, and showing little tendency to form a distinct stem. This species offers, perhaps, the most remarkable example of limited geographical distribution in the group. The Honey-scented Eucalypt (*E. melliodora*) is what is called, among such giants, a middle-sized tree, exceptionally attaining a height of some 200 feet; it will live on poor soil. In an official report presented in 1869 to the Victorian Parliament, Dr. Mueller pointed out that one ton weight of its branches and leaves, if gathered fresh, would yield about 2 lb. 12 oz. of pure potash, and a much larger quantity of crude pearl-ash. Another species, known from its odour as the "peppermint tree" (*E. odorata*), would seem to be a great favourite with a destructive nocturnal cockchafer. Through the immense clearings effected for agricultural settlements, the number of insect-eating birds has greatly diminished, and the increase of this species of Melolontha is not properly kept in check. They prey on the foliage of this Eucalypt, and Mr. Otto Tepper, writing in the *Transactions* of the Philosophical Society of Adelaide (February, 1878), states that it is being extensively destroyed from this fact.

The plates accompanying the descriptions of the species published in these decades give ample details of the leaves, flowers, and fruits of the species; they appear, so far as the stems with inflorescences are concerned, to be perhaps a little too stiff and formal. Sometimes details of the peculiar wood structures are added, and on one special plate transverse sections of the anthers of some fifty-eight species are figured. The London agents for this work are Messrs. Trübner and Co.

OUR BOOK SHELF

A Short Geography of the British Islands. By John Richard Green, M.A., LL.D., and Alice Stopford Green. (London: Macmillan and Co., 1879.)

"GEOGRAPHY, as its name implies, is an 'earth-picturing,' a presentment of earth, or a portion of earth's surface in its actual form, and an indication of the influences which that form has exerted on human history or human society. To give such a picture as this of our own country, in however short and simple a fashion, is the aim of the present work." Mr. and Mrs. Green have carried out the task they have here indicated in a masterly manner. The method they have adopted is the only scientific method on which a text-book of geography of this class can be constructed. Mr. Green, in his preface, speaks with just horror of the majority of text-books, with their dreary array of tables and "facts" and figures, which makes what ought to be one of the most interesting of lessons a burdensome and unprofitable penance.

In the first seven chapters the authors give a clear, instructive, and completely interesting sketch of the great physical features of our islands, and of their relation to the continent of Europe. The mountain groups, the uplands, the plains, and the rivers are brought before the student in their natural or scientific aspect, with just such details easily worked in as will give a clear picture of the various features. The counties are then grouped in their natural order, and each is treated after the same method as that followed in the general sketch. The great physical features are brought out first of all, the regions of the chief natural resources of the country indicated, and thus the mind of the pupil is prepared to understand how the political, social, and industrial features have come to be developed as we find them at the present day. "Facts" enough to satisfy any humane examiner are given, and the principal data and figures are collected in a few well-arranged tables. Great care has evidently been taken to obtain accurate and recent information both with regard to physical geography and topographical, industrial, and other statistics. Besides four coloured maps, there are twenty-four special sectional maps appropriately introduced throughout the book, which must prove of great use in impressing the facts upon the mind of the learner. We trust the Geography will be largely introduced into our schools; we are sure that the scholar at least would welcome it. Its style and method, moreover, render it attractive and instructive reading to those who have long left the school of their childhood behind.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Visibility of Mercury to the Naked Eye

IN NATURE, vol. xxi. p. 474, I find the following: "Mercury was seen at Paris on May (meant for March) 10 and 11 with the naked eye, owing to the transparency of the atmosphere and the great elongation of the planet. . . . The observation was mad by MM. Henry brothers at the Paris Observatory."

Must not "the transparency of the atmosphere" have more to do with the visibility of this planet than is usually supposed? The leading circumstances affecting the question, the amount of the planet's elongation, the inclination of the ecliptic in which it is situated to the horizon, heliocentric latitude, &c., being of course the same at each apparition in England, on the Continent, and in North America, how shall we otherwise account for some of the facts of the case? The remark is current respecting Copernicus that he never obtained a view of Mercury. And perhaps the general impression as to its visibility—that it can be seen only at the most favourable junctures, and for but a few days at a time—is reflected in the quotation above.

As a contribution to the question as it may be affected by the variable element of *climate, atmosphere*, I tabulate herewith the results of several years' careful though not thoroughly systematic observation of the planet at this geographical position, latitude 44° 53′ N., longitude 93° 05′ W., elevation 800 feet above sea-level:—

Year.	Time observed.	Days.	G. Elong. ° ′	Date.
1877	April 29 to May 11	13	21 5	May 3
1878	Sept.-Oct.	—	17 53	Sept. 26
1879	Jan. 7 to Jan. 29	22	24 03	Jan. 16
1880	Feb. 29 to March 19	20	18 22	March 10

It will be observed from the table that I followed Mercury with the naked eye at its last appearance in the west (when it was seen in Paris), from February 29 to March 19. I had intended to look for it a day sooner, February 28, as a crucial test as to how early it could be seen at that apparition, for it came into conjunction with Jupiter that day and would be approximately pointed out by the latter planet. But the state of the sky would not permit. Looking for Jupiter the next evening, so as to take bearings from him, I saw Mercury first, over a degree to the north-east of where Jupiter was when found. So I am confident that Mercury was within reach of the naked

eye the evening before at conjunction, save that clouds intervened. And this one day added to the twenty days actually recorded would make the period of visibility on this occasion three full weeks.

At the brightest the planet was fully equal to a 1st magnitude star, and for more than a week as bright as *a* Arietis, two hours to the east of it, with which I frequently compared it. It was brighter than Saturn (also in the twilight) for several evenings, and was seen casually, as any other star would be seen, as I came up town from business, for more than a week. As a friend of mine remarked, "it could be seen with half an eye."

As regards the earlier observations of the table, it will be noted that the planet was seen for thirteen days in the spring of 1877, though first looked for only five days before it reached its greatest eastern elongation. It was again beautifully seen several mornings near the close of September, 1878, coming twice into conjunction with Venus during that time, though the observations were not continued so as to try how long it could be followed.

Finally, in January, 1879, though the position of the ecliptic was not favourable, an elongation of over 24° and splendid skies enabled me to follow Mercury for twenty-two days in succession, or while he made a full one-fourth of a revolution round the sun!

If any interest attaches to this communication it will surely not be from a superfluous attempt to show that Mercury at special times becomes visible to the naked eye; but rather from its giving certain definite facts as to the exact *length of time* the planet has been observed, at the several apparitions indicated. The astronomical conditions of these returns of the planet may be made out with the help of an ephemeris and a celestial globe. I need only add that the observations were made in a climate where hours favourable for astronomical work may frequently be numbered by the hundred monthly, and own that the conditions of sky and atmosphere under which they were made were generally favourable to the best results. T. D. SIMONTON

St. Paul, Minnesota, U.S.A., May 1

Specialised and United Palæontological Research

In your report of Prof. Huxley's lecture on "The Coming of Age of the Origin of Species" there was one sentence which was pregnant with import to every true devotee of natural history and to every believer in the doctrine of evolution, to wit, that "primary and direct evidence in favour of evolution can be furnished only by palæontology."

Knowing that this is so, I ask, Do there exist amongst all our scientific associations delegated committees whose function it is to watch and foster palæontological research by every possible means? Seeing that so much depends on this kind of evidence, it is surprising that we hear so little of the results of any united efforts in this direction. What we generally hear of are the outcome mostly of private and individual inquiry. And since so much has already been done in this field of investigation by mere individual effort that the "missing links" between widely separated groups of the higher mammalia (not including man) have been discovered so abundantly that it can be said with respect to these, in the words of Prof. Huxley, "Evolution is no longer a speculation, but a statement of historical fact"—since this is the result of private and individual effort, what might not be achieved by united and organised research!

It is a truism that division of labour is the best means of specialising and perfecting any work, and an equally trite saying, that "union is strength;" yet in this, one of the most important of all the fields of biological study, we do not hear of a palæontological society or committee.

What could such a society or committee effect? it may be asked. Would it be expected to take hammer, pickaxe and spade in hand and wander over the wide world in exploration? Certainly not. But remaining at home, it could direct the efforts of private explorers, delegate officers of its own, equipped with the means of questioning the geological record in different parts of the globe, unite with kindred associations in solving problems too arduous for the single resources of one society, dividing alike the expenses and the spoil. Surely it would gratify the heart of every naturalist to learn if palæontological research had assumed this serious and energetic form.

How many opportunities are allowed to slip that might be turned to excellent account! Wars are carried on in countries as yet geologically unexplored, and for want of such a society as I have named there has been no one employed to accompany our armies in the cause of this branch of science. Railways and other engineering works have been carried out in such regions, but no one has been employed to watch the operations in the name of palæontology. Travellers go and return without having been furnished with data to guide researches that might have been intelligently prosecuted in the cause of science.

Will not our leaders in natural science arouse themselves to organised and specialised research in this all-important field of palæontology? W. S. DUNCAN

Stafford, May 29

The Meteorology of South Australia

[WE have been asked to publish the following correspondence on an article on this subject in NATURE, vol. xxi. p. 281.]

South Australia, the Treasury, Adelaide, April 15, 1880

SIR,—I have to thank you for the extract from NATURE, inclosed in your despatch No. 7,842, dated January 31 last, which was duly referred to the Honorable the Minister of Education, and has been perused by the Postmaster-General, &c., and observer, Mr. Todd, C.M.G., a copy of whose observations and remarks upon this subject I now forward for your information and that of the Editor of NATURE. I am, sir, your obedient servant, (Signed) C. MANN

Sir Arthur Blyth, K.C.M.G., Agent-General for South Australia, London

Post and Telegraph Department

Memo. on Letter from Agent-General

METEOROLOGICAL OBSERVATIONS

The writer of the article in NATURE had evidently not received the volume for 1878, but only the monthly numbers. In the volume, as the Agent-General, to whom I have sent a copy, will see, I have given the results of the observations at Port Darwin, Alice Springs, Eucla, Cape Borda, Mount Gambier, and Cape Northumberland. As the Minister is aware, I have recommended that instruments should be supplied to several additional places, which will really give effect to what the writer in NATURE very properly urges. The extent and form in which the observations made at our institutions should be published require consideration on the score of economy of printing; and, as the Minister is aware, the observatory is altogether undermanned for the work now done, and if it were not for my own personal exertions in doing that which might be intrusted to assistants, we could not do what is done. With regard to the other suggestion, I had previously decided on correlating the rainfall and wheat-yield in different districts, in addition to the table, which takes the colony as a whole, now given.

The form in which our observations are published and discussed appears to give general satisfaction, and this will be greatly increased when we have the continuous self-recording instruments I have recommended should be obtained.

April 4 (Signed) C. TODD
P. M. G. and Supt. T.

[Mr. Todd is correct in supposing that the volume for 1878 was not before us—not having been then received—in writing the article on the "Meteorology of South Australia" in NATURE, vol. xxi. p. 281, but only the monthly numbers. The volume has, however, been received quite recently, which, in view of the highly important additions it contains, referred to by Mr. Todd, we shall take an early opportunity of noticing. It gives us the highest satisfaction to learn that of the two points we drew attention to half a year ago, the one relating to the establishment of additional stations had not only been resolved on, but actually carried out in the beginning of 1878, and as regards the other one, referring to the correlating of the rainfall and the wheat-yield in different districts, in addition to the table which deals with the colony as a whole, it had previously been decided by Mr. Todd to discuss the data in the manner suggested.—ED.]

Comparative Curves in Terrestrial Magnetism

As the comparison of curves obtained at distant stations is at present one of the most important desiderata for the study of terrestrial magnetism, I forward to you traces of two photographs obtained on March 17 last at Vienna and at Stonyhurst. The storm is a remarkable one, and the curves offer a striking illustration of the simultaneous action of the disturbing force on

two magnets many miles apart. The action of the force appears to have been somewhat more vigorous at Stonyhurst than at Vienna, yet not only the great inflections, but even the slight irregularities of the curves were synchronous.

The trace of the Vienna magnetograph is taken from the May number of the *Zeitschrift der österreichischen Gesellschaft für Meteorologie*, kindly forwarded by Dr. Hann.

The range between the maximum and primary minimum at 5h. 45m. p.m. G.M.T. was 33′·7 at Vienna, and 42′·1 at Stonyhurst; and between the same maximum and the secondary minimum at 10h. 45m. p.m. was 24′·1 at Vienna, and 34′·0 at Stonyhurst.

Both the self-recording magnetographs were made by Adie, and the time-scale is the same for both curves; it is therefore very easy to identify the synchronous movements.

At Stonyhurst G.M.T. is adopted, and the longitude of Vienna is 1h. 5m. 31·3s. E. of Greenwich. S. J. Perry

Stonyhurst Observatory, May 27

Luminous Painting

Nil novi sub sole.—The Japanese, nine hundred years ago, seem to have been practically acquainted with the art of luminous painting, and thus to have anticipated Mr. Balmain. In looking through the article "ye" (pictures) in the Sinico-Japanese Encyclopædia, "Wakan san sai dzu-ye" (illustrated Description of the Three Powers, *i.e.*, Heaven, Earth, and Man), I recently came upon a passage, of which the following slightly condensed rendering may perhaps be of some interest to your readers:—

"In the Rui-yen (Lei-yuen, Garden of Sundries—a sort of Chinese Collectanea) we read of one Sü Ngoh, who had a picture of an ox. Every day the ox left the picture-frame to graze, and returned to sleep within it at night. This picture came into the possession of the Emperor T'ai Tsung, of the Sung dynasty (A.D. 976-998), who showed it to his courtiers, and asked them for an explanation, which none of them, however, could give. At last a certain Buddhist priest said that the Japanese found some nacreous substance within the flesh of a kind of oyster they picked up when the rocks were bared at low tide, and that they ground this into colour-material, and then painted pictures with it which were invisible by day and luminous by night."

"No doubt," adds the author of the Encyclopædia, "when it is said that the ox left the picture-frame during the day to go a-grazing, it is meant simply that during the day the figure of the ox was not visible." Fredk. V. Dickins

Brain Dynamics

There are probably among the readers of Nature some believers in the Freedom of Volition, to whom the discussion on the above subject has not hitherto appeared to reach the knottiest point of the controversy.

The more old-fashioned supporters of the doctrine of Free Will frequently insisted on the sense of Responsibility as the crucial proof that the will is free, probably because few of their opponents were ready to face the possible, or supposed, moral consequences of the denial of responsibility. The proof is essentially weak, and Mr. Romanes has well exhibited its weakness in Nature, vol. xxii. p. 76. His "Prince of Denmark" has indeed so little of method in his madness that I am not disposed to think it curious that both Prof. Clifford and Mr. Tolver Preston should have left him out of their play. He may well exclaim: "What should such fellows as I do, crawling between earth and heaven? We are arrant knaves all; believe none of us." Surely the sense of Responsibility is not the origin, but is one of the results of the Sense of Freedom. Logically the Sense of Freedom is the justification of the sense of responsibility. Historically it is, no doubt, its antecedent; for while both are, as much as any other faculties of brute and man, results of evolution, the refinement of the conception of morality, and therefore probably the conception itself, has evidently originated long after the consciousness of volition. Experimentally the sense of responsibility is weakened or destroyed, either psychologically, as where the freedom of the actor is controlled, or physiologically, as where volition is suspended in sleep, or is impaired by lesion of the anterior lobes of the brain, in all which cases the sense of responsibility suffers corresponding loss. It seems to me strange that Mr. Romanes should suppose the doctrine of Free Will to have been conceived and continued in order to justify that Moral Sense which is essentially a consequence of it (though capable finally of being presented as one among other motives in certain acts of volition). It lies with those who think with Mr. Romanes to account, on their own hypothesis, for the development of so universal, obtrusive, irrational, and indeed "nonsensical" an instinct as, according to that hypothesis, the sense of responsibility is. Others will see in it a result of the Sense of Freedom of Volition, when combined with the intellectual perception of the consequences, to the individual or to the race, of human acts (the latter perception being the cumulative result of inherited experiences). This Sense of Freedom of Volition is the real Hamlet.

We possess, or appear to ourselves to possess, the consciousness of the power of choosing between alternative motives. It is unsafe merely to give the lie direct to this consciousness, lest we thereby destroy the validity of the evidence, also derived through consciousness, of all those facts on which any law of nature, and Causal Sequence itself, is based. The consciousness of power is derived from the sense of work done, as against resistance, *e.g.*, the consciousness of muscular power is derived from a class of sensations produced on the organism by resistance, these sensations being created by, and consequently associated with, the conversion of potential energy stored up in the brain into kinetic energy transmitted through the nerves and muscles, and it bears no psychological resemblance to the consciousness of sensations of which the brain is the passive recipient. Similarly, the consciousness of the power of volition is derived from the sense of work done, in this case wholly within the brain, in the selection between alternative motives, and it bears no psychological resemblance to the consciousness of the motives themselves. And so, too, just as the sense of lassitude is produced by excess of work done as against physical resistance, so is a sense of discomfort produced by expenditure of potential energy, when acts of volition are performed against powerful emotions.

It appears to me that the Necessitarian should be able on his part to show that this *sense of work performed in choosing between motives* is fictitious, or that the energy above mentioned has no existence. This will not be done solely by holding even the terrors of omnipotent Causal Sequence over the head of the advocate of Free Will. The latter considers volitions to be, not indeed "uncaused" in the sense of occurring without antecedent emotions, or without expenditure of energy in choosing between the emotions, yet not to be rigidly determined by those emotions. He need not inquire whether a man be "unfortunate" in the capricious character of human acts as compared with other phenomena. But he on his part has to show (and certainly no scientific mind will underrate the magnitude of the task) that phenomena of volition do, paradoxical as it may seem, constitute a class by themselves, their relation to physical causation being perhaps comparable to that in which the phenomena of life stand to the laws of inorganic chemistry, a relation of addition, not of contradiction. W. Clement Ley

I should like to state, in reply to Mr. George Romanes' letter (Nature, vol. xxii. p. 75), that the question of "Responsibility" was left out of my letter (Nature, vol. xxii. p. 29) partly because it seemed to me a separate or somewhat distinct subject, and partly from the fact that this matter had been already considered by me in connection with a paper on "Natural Science and Morality," to be published in the *Journal of Science* for July next; and to this, therefore, I would venture to refer those who may be interested in this question.

I may merely conclude by saying that, while otherwise fully endorsing Mr. Romanes' letter, there is only one point on which I should be disposed to disagree with him, viz., in regard to his suggested view that the doctrine of strict causal sequence in nature would tend to show the feelings of Responsibility, Praise, and Blame to be "destitute of any rational justification." For there appear to me to be grounds for believing that a scientific and rational explanation of these feelings exists.

London, June S. Tolver Preston

Vortex Atoms

While thanking Mr. G. H. Darwin for his observations on one or two passages in my paper "On the Physical Aspects of the Vortex-Atom Theory," which, as they stand, may no doubt tend to convey an inexact impression, I may state that the illus-

tration of a pipe was used with the endeavour to aid the conceptions in some respects, rather than for rigid accuracy of comparison. The idea of the exterior fluid being *at rest* was subsequently guarded against by stating that it had "important functions" to perform. In regard to the fact of only mentioning "friction" as an element of resistance in a totally immersed body, I wished rather to convey the general idea that if no *energy* were given to the molecules of the surrounding liquid at the passage of the immersed body, there would be no "resistance." The object of the article was, however, not so much to lay stress on these points as to notice certain, perhaps less appreciated (*à priori*), aspects of the problem.

S. TOLVER PRESTON

Songs of Birds

YOUR correspondent "A. N." (*antè*, p. 97) does not seem to be aware that the best observers are nowadays agreed in believing that the hen cuckoo does not sing. Hence his suggestion in regard to the difference of note observed by Mr. Birmingham (*antè*, p. 76) hardly applies to the case in question.

ALFRED NEWTON

Magdalene College, Cambridge, June 6

I HAVE been in the habit of observing the notes of cuckoos, and have noticed that the musical interval is very variable. It is not always, or even often, amenable to our tempered scale, but may lie anywhere between a major 2nd and a 4th. The major 3rd seems to be about as frequent as the minor. The interval may vary in the same bird, as it is well known that the cuckoo's song alters greatly with the approach of summer.

Cup-marked Stones

ON a large block of fine-grained hard whitish sandstone near Burghead, Elgin, are forty-four cup-marks of various sizes, but all very finely formed. Four of the cups have channels or grooves of various lengths and running in different directions, but none to the edge of the stone. Five have one ring, and channels of various lengths, and in different directions. Four have got two rings and channels, and one has three rings and a channel. In some cases the rings are not complete, that is, they stop short on either side of the channel, but close to it. One cup has a simple ring.

From this example, and if I recollect the figures in Sir J. Y. Simpson's work, there seems to be but few cases in which the channels run to the edge of the stone.

Out of a considerable number of cup-marked stones partly on finely ice-polished rock surfaces and partly on detached blocks large and small, in Elginshire, this is the only one that has rings and grooves. A full description of these, with plans, I have nearly ready to lay before the Society of Antiquaries at one of their early meetings of next session.

JAMES LINN

Keith, June 2

THE DUMAS NUMBER.—In reply to numerous inquiries we may state that the portrait of M. Dumas should form the frontispiece to vol. xxi., and the article by Dr. Hofmann be placed after the index in the beginning of the volume.

ENERGY AND FORCE[1]

[ON March 28, 1873, Clifford delivered a Friday evening discourse on this subject at the Royal Institution. By some accident no trace of it, not even the date or title, appears in the printed *Proceedings*. Thus the lecture escaped notice when Clifford's literary and scientific remains were collected in the summer of last year. A few weeks ago I lighted on my own rough notes of it taken down at the time, probably the only record now in existence. These I have written out, with only so much alteration and addition (indicated by square brackets) as necessary to make them intelligible. The paper thus produced has been seen by Clifford's friend and mine, Mr. J. F. Moulton, who (besides his general competence in mathematical physics) was thoroughly acquainted with Clifford's mathematical work and ideas. Mr. Moulton has added, by way of introduction, some remarks founded on this intimate knowledge, which will explain the aims of the discourse and supplement the too meagre report which is all that I am able to reconstruct from my notes.—F. POLLOCK.]

This lecture was, I think, written as a protest against certain loose ideas that had become prevalent relating to energy, motion, and force. The discoveries as to the equivalence of the many forms of energy and the invariability of the total of energy in any system not operated on by external forces (one case of which is the whole material universe), had led philosophical writers and others to treat force as an entity with a separate existence like matter, and also, like it, indestructible. The error of thus treating force as an entity with a separate existence was not an unnatural one in those who had not much acquaintance with the theories of physics. No idea is more consonant with the ordinary modes of thought than that force is a something operating from without on a body, and producing effects thereupon in the shape of an alteration of its motion, so that the quasi-personification of force contained in the above does not appear to be in any way an unwarranted conception. The further step, which ascribes to force an indestructibility as absolute as that of matter, is due to a confusion in the terms used by mathematicians themselves in speaking of these subjects, for which they are to blame. Before the conservation of energy was fully formulated, mathematicians were acquainted with a particular case of the general principle, and it had received the name of conservation of force. This unfortunate appellation, with all its misleading tendencies, was often applied to the general principle when the latter first became known, and hence unscientific writers naturally assumed that force and energy were convertible terms and that they were alike indestructible. These erroneous conceptions had attracted Prof. Clifford's attention, and with his usual zeal for preserving scientific ideas from all taint, he set about correcting them. His mode of doing so is highly characteristic. He strikes straight at the root of the matter, and would have us at once cease to think of force as an entity at all. Indeed he goes so far as almost to warn us against tolerating the conception of a cause as distinguished from its effects.

All we know as to force and motion, he says, is that a certain arrangement of surrounding bodies produces a certain alteration in the motion of a body. It has been usual to say that this arrangement of surrounding bodies produces a certain force, and that it is the action of this force that produces the alteration of the motion. Why have this intermediate term at all? Why should we not go at once from the surrounding circumstances to the alteration of motion which follows? The intermediate term is only a mental inference either from the existence of the surrounding circumstances or from the occurrence of the alteration in the motion; and if we only accustom ourselves to pass from one to the other without its assistance, it will cease to be necessary, and like other useless mental conceptions, be gradually forgotten. And with it will pass all tendency to give to this useless mental phantom any such real and material qualities as indestructibility.

I was not present when the lecture was given, nor do I know otherwise than from these notes how Prof. Clifford carried out these ideas. But in conversation he had often discussed the matter with me, and made me fully acquainted with his views on the subject, so that I am able thus far to confirm the accuracy and completeness of these notes. It will be seen that he defines force as

[1] An unpublished discourse by the late Prof. Clifford. With an introductory note by J. F. Moulton.

"the change of momentum of a body considered as depending upon its position relative to other bodies," thus bringing into direct connection the surrounding bodies and the consequent alteration of motion and rendering the conception of force a superfluous one. In his concluding remarks as to whether we are directly conscious of force, there is the same tendency. He is well aware that such an attempt as his will be viewed with very little favour by the not unimportant school of philosophers who conceive that force is the only thing that we are directly conscious of, and thus he takes the opportunity to combat this idea.

The part of the lecture that refers to energy needs no special remark. He shows, in his usual clear style, at once how much and how little is contained in the law of the conservation of energy. So far from containing in itself the solution of all the changes in the universe, it tells us only one of the conditions that these must obey, and gives us very little information, if any, as to the particular results that follow from the causes that are at work. It is invaluable as a negative law. It enables us to reject with absolute certainty countless hypotheses that would otherwise be temptingly appropriate to elucidate the complexities of nature. But further than that it cannot go. It cannot distinguish between the innumerable hypotheses that satisfy it, of which, after all, only one can be true. J. F. M.

No mathematician can give any meaning to the language about matter, force, inertia, used in current text-books of mechanics.

The old definition of *force* contains the word cause. In the older writers this is a mere manner of speaking; thus Maclaurin defines velocity as the cause of a body changing its position. We now define it as the rate of change of position.

Causation is defined by some modern philosophers as unconditional uniformity of succession, *e.g.*, existence of fire follows from putting a lighted match to the fuel.

This idea must be got rid of to understand force. All universally true laws of nature are laws of co-existence, not succession. Thus, I want to move a thing and I push it, and motion follows. This suggests at first sight the conception of cause and effect being related in succession. But really you change the rate of motion of a thing *at the time* when you push it, not afterwards. So if you drop a thing from your hand, the letting go and the falling down are really simultaneous. Again, the change of motion of a terrestrial body is at every instant dependent on its distance from the earth's centre (though in practice this is neglected for small distances). In every case the law at work is seen to be a law of co-existence, not succession.

Momentum may be roughly described as quantity of motion. A body moving at a speed of say twenty miles an hour, has a certain quantity of motion. If the same body goes forty miles an hour there is twice as much motion; or if twice as much matter goes twenty miles an hour, there is also twice as much motion. Momentum is measured by the quantity of matter moving at a given rate (mass $\times$ velocity).

How is the quantity of matter measured if we compare bodies of different substances, such as wood and lead? Not by size: there is another scale by which the quantity of matter in a given body, without regard to the kind of matter, can be measured. [The existence of such a scale and the possibility of applying it are involved in the idea of *mass.*] The simplest method of applying that scale in practice is to weigh the two bodies to be compared at the same place.

Force cannot be explained without stating a law of nature concerning momentum, viz.:—

Suppose a body with a certain momentum to be the only body in the universe; it will go on with the same momentum.

If there is any change, there is another body, and the change depends on the position of that body.

The case of bodies in contact is no exception to this law, but only a particular case. Here the change of motion is called *pressure.* The case of bodies not in contact is illustrated by the motion of the earth about the sun [under the force of gravitation, as we call it].

In all cases change of motion is connected by invariable laws with the position of surrounding bodies. Force, then, has a definite direction [at every instant] at any point in space, and depends on the position of surrounding bodies, and may be described as the change of momentum of a body considered as depending upon its position relative to other things. It embodies the quality of direction as well as magnitude. In other words, it is a *quantity having direction.*

Force, defined as above, is not conserved at all. It may appear and disappear; it is continually being created and destroyed. "Conservation of force" is, mathematically speaking, a contradiction in terms.

Energy [is of two kinds: 1. Energy of motion; 2. Energy of position].

1. In a moving body we have a certain *quantity of motion* [as explained above under the head of momentum]. Thus in a moving railway train let the unit of motion be one carriage going at the rate of one mile per hour; then ten carriages going at the rate of twenty miles per hour have 200 units of motion. [The quantity of motion or momentum in a body may be regarded as travelling with the body, and] energy of motion is the *rate at which momentum is carried along.* [It depends on momentum and velocity jointly, and the energy of motion of a given body] is known when the velocity is known. In practice it is convenient to call the actual amount of energy of motion half this rate. It is expressed by $\frac{1}{2}mv^2$ [*i.e.*, $mv \times v$, not $m \times v^2$: Clifford, in conversation].

2. Energy of position is quite a different thing. If I take a book lying on the table and lift it up, and put it on the desk above the table, it acquires energy of position, and the energy acquired is measured by the weight [assuming gravity to be constant] of the book multiplied by the difference of height between the two positions. [Energy of position, like force, may be said to exist at any point of space, whether a body is there or not.] The difference of energy between two positions is the quantity of work that must be done to remove a body of unit mass from one position to the other.

When a body is let fall from a higher position to a lower one, it has, at the instant when it is let go, no energy of motion; but it gains, in falling, as much energy of motion as it loses energy of position. It is found that the *sum of energy of motion and energy of position is always constant.*

Force, we have seen, is a quantity which has direction. Energy is a quantity which can be greater or less, but has no direction. The name Energy is applied to two different quantities, of which we find the sum to be constant. This constancy is expressed by including them in the common name of Energy, and saying that energy is conserved, or is indestructible. This form of speech might be applied to other cases of alternate immortality, where one of two things comes into existence on the disappearance of the other.

Does the law of persistence of energy mean no more than this? Yes, [it means more when it is used to include the "correlation of physical forces]". Other qualities of bodies are connected with simple energy of motion and energy of position. Such is heat, which we find by experiment can be turned into work. Finding it convertible with energy, we call it a form of energy.

Here we have [it seems] three different things included: energy of motion, energy of position, heat. But as to

heat, it is further established by experiment that in this case the energy of motion does really persist as such. Thus a gas consists of molecules flying about with great velocity, rotating and vibrating, and so having energy of motion. All this energy of motion is what we call heat, and thus heat is a repetition of a known meaning of energy. Again, heat exists between a radiating body and the thing it warms; now the intermediate space is filled by the luminiferous ether, which, being elastic, has in its ultimate parts both energy of motion and energy of position. In these forms the heat exists in the space in question.

In the cases of heat and electricity the form of the persisting energy is pretty well ascertained. But there are cases in which we do not know if it is energy of motion or energy of position, such as that of *chemical energy*. In the burning of coal there is a falling together of carbon and oxygen [and heat is produced]; but we do not know in which of the two forms, if either, the energy which comes out as heat existed in the chemical process. For such a case the conservation of energy is only a probable statement (though of great probability) to the effect that in all cases where a physical quality is convertible with energy, that quality is itself either energy of motion or energy of position.

General Results.—Force is a quality of position, definite in magnitude and direction at any point; not constant.

Energy is the name of two different quantities.

1. Energy of motion, half the rate at which a body carries momentum.

2. Energy of position, defined by the statement of the law that the work done in getting from one position to another is the same by whatever path the change of position is made.

[The definition of these conceptions helps to clear up sundry questions of mixed physics and metaphysics.]

1. Is a physical force, such as the attraction of the earth, analogous to our "exertion of force" in muscular work? No, for the sensation of muscular effort is very complicated. It involves nerve and muscle, which we know not to be present in the simpler cases, *e.g.*, the motion of a stone let fall. To talk of *pushing* or *pulling* in such a case is a personification of external nature.

2. Are we directly conscious of force? It is often said in physical and metaphysical works that we are. It may be true, but it is at least premature. We do not *know* that the chemical changes in nerve-matter corresponding to consciousness are energy [only that they are *convertible with* dynamical energy]; much less do we know that they are force. If they are energy, it is energy of motion, not energy of position, since consciousness does not depend on the position of the nerve-matter [so my notes: *sed quære*].

3. Is mind a force? It is held by some that the will acts as the match to gunpowder, by setting loose a store of energy, the matter of the brain being in unstable equilibrium. But you cannot have in nature an absolutely unstable equilibrium [*i.e.*, an equilibrium capable of being upset by an infinitesimal force], because the universe is not at rest [and every motion in the universe produces a finite change, however small, in the resultant force at every point of space]. Therefore if mind is force, operating in the way suggested, it must be able to create a determinate quantity of energy. This is a supposition which, if true, would destroy its own evidence; for it would destroy the uniformity of nature, on which all possibility of inference ultimately rests.

[The discourse concluded by pointing out that even from a purely scientific point of view, metaphysical speculation is to be encouraged as a spur to science.]

ECHIS CARINATA

THOSE who are interested in the poisonous snakes of India may have an opportunity of seeing one of the most interesting and destructive of these reptiles, now in the Zoological Society's Gardens in Regent's Park.

The snake I refer to is a fine specimen of the *Echis carinata*, which has recently arrived from India, and is the first of its kind, I am told, that has been received alive in this collection. I think it is probable, however, that a snake so common in some parts of India must have been brought alive to England before; but at any rate it is rare, and sufficiently interesting to claim attention, especially as it is healthy, vigorous, and active, and readily shows its peculiar habits, in the attitude it assumes and the rustling sound it gives rise to by the friction of the carinated scales of one fold of its body against those of the other when alarmed, and in the aggressive position which it takes up when prepared to strike, which it does most viciously by launching out its head and the anterior part of its body from the centre of the convoluted folds into which it has arranged itself. There are, I believe, only two true vipers in India (though there are several Crotalidæ), the *Daboia russellii*, or chain viper, or ticpolonga, and the *Echis carinata*. The daboia is well known here, and there are, or have been lately, fine specimens in the Society's collection; but the echis is not so well known, though common enough in India.

It is much smaller than the Daboia, and is very active and dangerous. It is known in Sind as the "kuppur"; in other parts of the country as "phoorsa"; about Delhi it is "afäe," or "afai" (a word of Arabic origin). Russell calls it "horatta pam." It seldom attains more than the length of 20 to 22 or 23 inches; probably 15 or 16 inches is more common, and is from 2 to 2½ or 3 inches in circumference at the thickest part of the body.

It is very fierce and aggressive, always ready to attack. It throws itself into a double coil, the folds of which are in perpetual motion; the whole body does not necessarily change its place, and as they rub against each other they make a loud rustling sound, which may be mistaken for hissing. This is produced by the three or four outer rows of carinated scales, which are prominent and point downwards at a different angle to the rest; their friction against each other causes the loud rustling sound which gives notice of the presence of the echis, as does the rattle of the crotalus.

I have never heard this viper hiss; though the daboia does so loudly. It is of a brownish-grey colour, with white and dark spots, and a waving whitish band on either side of the body. On the head there is a peculiar mark something like a cross. Its fangs are very long and mobile, and its poison very active, destroying a fowl in two or three minutes. In Sind, and some other parts of India where it is very common, it causes considerable loss of human life, though I believe it is not so destructive on the whole as either the cobra or *Bungarus cæruleus* (Krait), which are more generally distributed over the peninsula. I have not seen it in Bengal, but it is common in the North-West Provinces, Punjab, Sind, and Central Provinces, and Southern India in the Carnatic, and about Madras.

Its aggressive aspect when roused, the vicious eye, its peculiar method of folding itself, the rustling of its scales, and the rapidity with which it strikes, make it, when living, an object of considerable interest.

In the same collection there is a fine specimen of another very rare colubrine venous snake, the *Ophiophagus elaps*, which gives an opportunity not often available even in India, where the snake is found only in certain localities, of studying its peculiar habits and food, which consists of other snakes. It is as deadly as the cobra, to which it is nearly allied; but from its comparative rarity and the nature of its habitat it does not contribute so largely to the death-rate as that snake or even as the little echis.

J. FAYRER

CONTRIBUTIONS TO MOLECULAR PHYSICS IN HIGH VACUA[1]

II.

IT has been shown that the stream of molecules are shot off from the negative pole in a negatively charged condition, and their velocity is owing to the mutual repulsion between the similarly electrified pole and molecules. It became of interest to ascertain whether lateral repulsion was exerted between the molecules themselves. If the stream of molecules coming from the negative pole carried an electric current, two parallel rays should exert mutual attraction; but if nothing of the nature of an electric current was carried by the stream, it was likely that the two parallel rays would act simply as negatively electrified bodies and exert lateral repulsion. This was not difficult to put to the test of experiment.

A tube was made with two flat aluminium terminals, *a b*, close together at one end, and one terminal, *c*, at the other, as shown in Fig. 11. Along the centre of the tube, cutting the axis obliquely, is a screen of mica, painted over with a phosphorescent powder, and between the screen and the double poles, *a b*, is a disk of mica crossing the axis of the tube, and therefore nearly at right angles to the phosphorescent screen. In this mica disk are two slits—one opposite each pole *a* and *b*—running in such a direction that the molecular streams emanating from *a* and *b* when made negative shall pass through the slits, forming two horizontal sheets. These sheets striking against the oblique screen will be made evident as two horizontal lines of light. The poles *a* and *b* were somewhat bent, so that the lines of light were not quite parallel, but slightly converged. The tube being properly exhausted, the pole *a* was made negative, and *c* positive, the lower pole *b* being left idle. A sharp ray of phosphorescent light shot across the screen along the line *d f*. The negative wire was now transferred from *a* to *b*, when a ray of light shot along the screen from *e* to *f*. The two poles *a* and *b* were now connected by a wire, and the two together were made the negative pole. Two lines of light now shone on the screen, but their positions, instead of being, as before, *d f* and *e f*, were now *d g* and *e h*, as shown by the dotted lines. The wire joining the poles *a b* was removed, and the pole *a* made negative; the ray from it followed the line *d f* as before. While the coil was working, another wire hanging loose from the pole *b* was brought up to *a*, so as to make them both negative. Instantly the ray *e h* shot across the screen, and simultaneously the ray *d f* shifted its position up to *d g*. The same phenomena were observed when the pole *b* was connected with the coil, and contact was alternately made and broken with *a*; as the ray *d g* shot across, the ray *e f* dipped to *e h*.

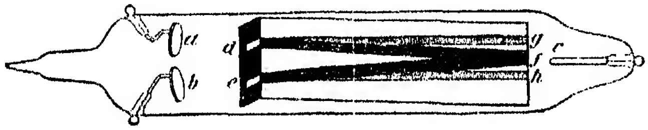

Fig. 11.

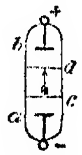

Fig. 12.

These experiments show that two parallel rays of molecules issuing from the negative pole exert lateral *repulsion*, acting like adjacent streams of similarly-electrified bodies. Had they carried an electric current they should have attracted each other, unless, indeed, the attraction in this case was not strong enough to overcome the repulsion.

Many experiments have been made to ascertain the law of the action of magnets and of wires carrying currents, on the stream of molecules.

As an indicator, a small tube, as shown in Fig. 12, was employed. The two poles are at *a* and *b*, *a* being the negative. At *c* is a plate of mica with a hole in its centre, and at *d* is a phosphorescent screen. A sharp image of the hole in the mica is projected on the centre of *d*, and the approach of a magnet causes this bright spot to move to different parts of the phosphorescent screen.

A large electro-magnet was used, actuated by two Grove's cells, and the indicator tube was carried round the magnet in different positions and the results noted. The molecular stream when under no magnetic influence passes along the axis of the tube, as shown by the small arrow (Fig. 12). It will be seen that the indicator can occupy three different directions in respect to the magnet. The magnet being held horizontally, the direction of the molecular stream may be parallel to the axis, tangential to it, or at right angles to it. In either of these positions, also, the stream may be directed one way or the other (by turning the tube round endwise). In these different positions various results are obtained which are easily illustrated with a solid model, but are somewhat complicated to explain by means of flat drawings. They are fully described in the paper.

A long tube was made similar to the small indicator shown in Fig. 12, but having a molecular trajectory six inches long. It was only exhausted to the point at which the image of the spot was just seen sharply defined on the screen, as at higher exhaustions the action of magnetism is less. The phosphorescent screen was divided into squares for convenience of noting the deflection of the spot of light. So sensitive was this to magnetic influence, that when the tube was placed parallel to the earth's equator the earth's magnetism was sufficient to cause the spot to move 5 millims. away from the position it occupied when parallel to the dipping needle (in which position the earth's magnetism did not appear to act). When held equatorially and rotated on its axis, the spot of light, being always driven in one direction independent of the rotation of the tube, appeared to travel round its normal position in a circle of 10 millims. diameter.

I have long tried to obtain continuous rotation of the molecular rays under magnetic influence, analogous to the well-known rotation obtained at lower exhaustions. Many circumstances had led me to think that such rotation could be effected. After many failures an apparatus was constructed as follows, which gave the desired results:—

A bulb (Fig. 13) was blown of German glass, and a smaller bulb was connected to each end of the larger bulb by an open, very short neck. At each extremity was a long aluminium pole projecting partly into the large bulb and turned conical at the end. After good exhaustion the passage of an induction current through this apparatus fills the centre bulb with a very fine green light, whilst the neck surrounding the pole which happens to be negative is covered with two or three dark and bright patches in constant motion, following each other round first one way and then the other, constantly changing direction and velocity, sometimes dividing into other patches, and at others fusing together into one. After a

[1] "Contributions to Molecular Physics in High Vacua. Magnetic Deflection of Molecular Trajectory; Laws of Magnetic Rotation in High and Low Vacua; Phosphorogenic Properties of Molecular Discharge." By William Crookes, F.R.S. (Extracts from a paper in the *Philosophical Transactions* of the Royal Society, Part 2, 1879.) Continued from p. 104.

little time, probably owing to the magnetism of the earth, or that of the core of the induction coil not far off, the movements sometimes become more regular, and slow rotation takes place. The patches of light concentrate into two or three, and the green light in the bulb gets more intense along two opposite lines joining the poles forming two faintly outlined patches, which slowly move

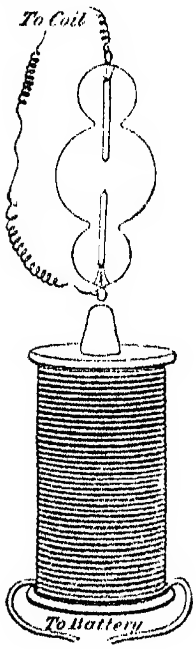

FIG. 13.

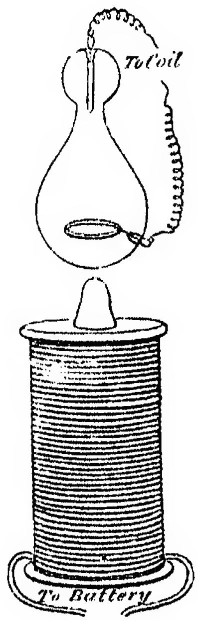

FIG. 14

round the bulb equatorially, following each other a semicircumference apart.

An electro-magnet placed beneath in a line with the terminals (Fig. 13) converts these undecided movements into one of orderly rotation, which keeps up as long as the coil and magnet are at work.

In order to compare accurately the behaviour of the molecular streams at high exhaustions with that of the ordinary discharge through a moderately rarefied gas, another tube was taken having the upper pole an aluminium wire, and the lower one a ring, Fig. 14. It was only exhausted to such a point that the induction spark should pass freely from one pole to the other in the form of a luminous band of light, this being the form of discharge usually considered most sensitive to magnetic influence. This tube was also mounted over an electro-

FIG. 15.

magnet, and the two sets of apparatus being actuated successively with the same coil and battery, the following observations were made.

The tubes will be distinguished by the terms "high vacuum" (Fig. 13) and "low vacuum" (Fig. 14). The rotation produced in each tube will be recorded in the direction in which it would be seen by an observer above, looking vertically down on the tube, his eye being in a line with the terminals and with the axis of the magnet. When the rotation thus viewed is in the direction of the hands of a watch, it is called *direct;* the opposite movement being called *reverse.* To facilitate a clear appreciation of the actions, an outline sketch (Fig. 15) accompanies each experiment. The shape of the tube shows whether it is the high or low vacuum tube, and the letter D or R shows the direction of rotation.

a. Upper pole of electro-magnets *north.*
Induction current passing through tubes so as to make the top electrode *positive.*
Rotation in the high vacuum *direct.*
Rotation in the low vacuum *direct.*

b. Upper pole of magnets *north.*
Top electrode of tubes *negative.*
Rotation in high vacuum *direct.*
Rotation in low vacuum *reverse.*

c. Upper pole of magnets *south.*
Top electrode of tubes *positive.*
Rotation in high vacuum *reverse.*
Rotation in low vacuum *reverse.*

d. Upper pole of magnet *south.*
Top electrode of tubes *negative.*
Rotation in high vacuum *reverse.*
Rotation in low vacuum *direct.*

These experiments show that the law is not the same at high as at low exhaustions. At high exhaustions the magnet acts the same on the molecules whether they are coming to the magnet or going from it, the direction of rotation being entirely governed by the magnetic pole presented to them, as shown in cases *a* and *b* where the north pole rotates the molecular stream in a *direct* sense, although in one case the top electrode is positive and in the other negative. Cases *c* and *d* are similar; here the magnetic pole being changed, the direction of rotation changes also. The direction of rotation impressed on the molecules by a magnetic pole is opposite to the direction of the electric current circulating round the magnet.

The magnetic rotations in low vacua are not only fainter than in high vacua, but they depend as much on the direction in which the induction spark passes through the rarefied atmosphere, as upon the pole of the magnet presented to it. The luminous discharge connecting the positive and negative electrode carries a current, and the rotation is governed by the mutual action of the magnet on the perfectly flexible conductor formed by the discharge.

In high vacua, however, the law is not the same, for in cases *b* and *d* similar arrangements produce opposite rotations in high and in low vacua. The deflection exerted by a magnet on the molecular stream in a high vacuum may be compared to the action of a strong wind blowing across the line of fire from a mitrailleuse. The deflection is independent of the to-and-fro direction of the bullets, and depends entirely upon the direction of the wind.

I have already mentioned that platinum will fuse in the focus of converging molecular rays projected from a concave pole. If a brush of very fine iridio-platinum wire, which has a much higher fusing point than platinum, be used to receive the molecular bombardment, a brilliant light is produced, which might perhaps be utilised.

A piece of apparatus was constructed in which a plate of German glass was held in the focus of the molecular bombardment. The vacuum was so good that no hydrogen or other lines could be seen in the spectrum of the emitted light. The focus was now allowed to play on the glass, when the glass soon became red hot. Gas appeared in the tube, and hydrogen lines now were visible in the spectrum. The gas was pumped out until hydrogen disappeared from the spectrum. It was now possible to heat the glass to dull redness without hydrogen coming in the tube; but as soon as the heat approached the fusing point

the characteristic lines appeared. It was found that however highly I heated the glass and then pumped the tube free from hydrogen, I had only to heat the glass to a still higher temperature to get a hydrogen spectrum in the tube. I consider the hydrogen comes from vapour of water, which is obstinately held in the superficial pores, and which is not entirely driven off by anything short of actual fusion of the glass. The bubbles noticed when the disintegrated and fused surface of the tube was examined under the microscope are probably caused by escaping vapour of water.

When the negative discharge has been playing for some time on German glass, so as to render it strongly phosphorescent, the intensity of glow gradually diminishes. Some of this decline is due to the heating of the glass or to some other temporary action, for the glass partially recovers its property after rest; some is due to a superficial change of the surface of the glass; but part of the diminished sensitiveness is due to the surface of the glass becoming coated with this brown stain.

The luminous image of a hole in a plate of mica was projected from a *platinum* plate used as a negative pole, to the side of a glass bulb. The coil was kept playing for some time until the inside of the bulb was thoroughly darkened by projected platinum. Although a bundle of molecular rays could be seen all the time passing from the platinum through the hole in the mica to the glass, where it shone with a bright green light, I could detect no trace of extra darkening when the part of the glass formerly occupied by the green spot was carefully examined. Platinum is a metal which flies off in a remarkable manner when it forms the negative pole. It therefore appears from this experiment that the molecular stream does not consist of particles of the negative pole shot off from it.

One of the most striking of the phenomena attending this research has been the remarkable power which the molecular rays in a high vacuum possess of causing phosphorescence in bodies on which they fall. Substances known to be phosphorescent under ordinary circumstances shine with great splendour when subjected to the negative discharge in a high vacuum. Thus, a preparation of sulphide of calcium, much used now in Paris for coating clock faces which remain luminous after dark, is invaluable in these researches for the preparation of phosphorescent screens whereon to trace the paths and trajectories of the molecules. It shines with a bright blue-violet light, and when on a surface of several square inches is sufficient to light up a room. Modifications of these phosphorescent sulphides shine with a yellow, orange, and green light.

The only body I have yet met with which surpasses the luminous sulphides both in brilliancy and variety of colour is the diamond. Most of these gems, whether cut or in the rough, when coming from the South African fields, phosphoresce of a brilliant light blue colour. Diamonds from other localities shine with different colours, such as bright blue, pale blue, apricot, red, yellowish-green, orange, and bright green. One beautiful green diamond in my collection when phosphorescing in a good vacuum gives almost as much light as a candle; the light is pale green—almost white. A beautiful collection of diamond crystals kindly lent me by Prof. Maskelyne phosphoresce with nearly all the colours of the rainbow, the different faces glowing with different shades of colour.

Next to the diamond, alumina in the form of ruby is perhaps the most strikingly phosphorescent stone I have examined. It glows with a rich, full red; and a remarkable feature is that it is of little consequence what degree of colour the earth or stone possesses naturally, the colour of the phosphorescence is nearly the same in all cases; chemically precipitated amorphous alumina, rubies of a pale reddish-yellow, and gems of the prized "pigeon's blood" colour, glowing alike in the vacuum, thus corroborating E. Becquerel's results on the action of light on alumina and its compounds in the phosphoroscope (*Annales de Chimie et de Physique*, sér. 3, vol. lvii.). Nothing can be more beautiful than the effect presented by a mass of rough rubies when the molecular discharge plays on them in a high vacuum. They glow as if they were red hot, and the illuminating effect is almost equal to that of the diamond under similar circumstances.

By the kindness of M. Ch. Feil, who has placed large masses of his artificial ruby crystals at my service, I have been enabled to compare the behaviour of the artificially formed crystals with that of the natural ruby. In the vacuum there is no difference whatever; the colour of the phosphorescence emitted by M. Feil's crystals is of just as an intense a colour, and quite as pure in character, as that given by the natural stone. This affords another proof, if one were needed, that Messrs. Fremy and Feil have actually succeeded in the artificial formation of the veritable ruby, and have not simply obtained crystals which imitate it in hardness and colour.

The appearance of the alumina glow in the spectroscope is remarkable. There is a faint continuous spectrum ending in the red somewhere near the line B; then a black space, and next an intensely brilliant and sharp red line to which nearly the whole of the intensity of the coloured glow is due. The wave-length of this red line, which appears characteristic of this form of alumina, is 689·5 m.m.m., as near as I can measure in my spectroscope; the maximum probable error being about ± ·3.

This line coincides with the one described by E. Becquerel as being the most brilliant of the lines in the spectrum of the light of alumina, in its various forms, when glowing in the phosphoroscope.

This coincidence affords a good proof of the identity of the phosphorescent light, whether the phosphorescence be produced by radiation, as in Becquerel's experiments, or by molecular impact in a high vacuum.

I have been favoured by my friend Prof. Maskelyne with the following notes of results obtained on submitting to the molecular discharge various crystals which he lent me for the purpose of these experiments:—

"Diamond crystals. A very small crystal, exhibiting large cube faces with the edges and angles truncated, was of a rich apricot colour, the dodecahedral faces of a clear yellow, and the octahedral of another yellow tint. No polarisation of the light was detected. Some were opaque; some gave a bluish hazy light.

"Emerald. A small hexagonal prism gave out a fine crimson-red colour. The light was polarised, apparently completely, in a plane perpendicular to the axis; this would correspond therefore to extraordinary rays which in emerald, as a negative crystal, represent the quicker rays vibrating presumably parallel to the optic axis of the crystal.

"Other emeralds behaved in the same way, though the illumination in two others experimented with appeared confined more particularly to one end—the end opposite to that at which the crystals presented some (in one instance fine) terminal faces.

"Beryls exhibited no corresponding phenomena.

"Sapphires gave out a bluish-grey light, distinctly polarised in a plane perpendicular to the axis. In this case, again, the ray developed corresponds to the extraordinary or quicker ray.

"Ruby gives out a transcendently fine crimson colour, exhibiting no marked distinction in the plane of its polarisation, though in one part of a stone the colour was extinguished by a Nicol prism with its long diagonal parallel to the axis of the crystal. Here, therefore, also the light was that of the extraordinary ray.

"It seemed desirable to determine the nature of the phenomena in the case of positive crystals, and accord-

ingly crystals of quartz, phenakite, tinstone, and hyacinth (zircon), were placed in a tube and experimented on.

"The only crystals that gave definite results were tintone and hyacinth. A small crystal of the former mineral glowed with a fine yellow light, which was extinguished almost entirely when the long diagonal of the Nicol was perpendicular to the axis of the crystal.

"Here, therefore, the plane of polarisation of the emitted light was parallel to the axis of the crystal, and here it is again the quicker, though in this case (of an optically positive crystal) it is the ordinary ray which corresponds to the light evoked by the electric stream.

"So far, then, the experiments accord with the quicker vibrations being called into play, and therefore in a negative crystal the extraordinary and in a positive crystal the ordinary is the ray evoked.

"A crystal of hyacinth, however, introduced a new phenomenon. In this optically positive crystal the ordinary ray was of a pale pink hue, the extraordinary of a very beautiful lavender-blue colour. In another crystal, like the former from Expailly, the ordinary ray was of a pale blue, the extraordinary of a deep violet. A large crystal from Ceylon gave the ordinary ray of a yellow colour, the extraordinary ray of a deep violet hue.

"Several other substances were experimented on, including some that are remarkable for optical properties, among which were tourmaline, andalusite, enstatite, minerals of the augite class, apatite, topaz, chrysoberyl, peridot, garnets of various kinds, and parisite. So far, however, these minerals have given no result, and it will be seen that the crystals which have thus far given out light in any remarkable degree are, besides diamond, uniaxal crystals (an anomaly not likely to be sustained by further experiment); and the only conclusion arrived at is, that the rays whose direction of vibration corresponds to the direction of maximum optical elasticity in the crystal are always originated where any light is given out. As yet, however, the induction on which so remarkable a principle is suggested cannot be considered sufficiently extended to justify that principle being accepted as other than probable."

WILLIAM CROOKES

ON THE LAW OF FATIGUE IN THE WORK DONE BY MEN OR ANIMALS

THE Rev. Dr. Haughton, of Trinity College, Dublin, has recently brought to a conclusion a series of papers on Animal Mechanics published in the *Proceedings* of the Royal Society. The ninth of these papers was appointed the Croonian Lecture for the present year, and the tenth paper closes the series.

The most important subject involved in these papers is the experimental determination of the law that regulates fatigue in men and animals, when work is done, so as to bring on fatigue.

Many writers, such as Bouguer, Euler, and others, have laid down mathematical formulæ, connecting the force overcome with the velocity of the movement; but these theoretical speculations have never received the assent of practical engineers.

Venturoli points out a method of observations and experiments which would serve to determine the form of the function which expresses the force in terms of the velocity, after which a few carefully planned experiments would determine the constant coefficients; and he adds that "such a discovery would be of the greatest usefulness to the science of mechanics, upon which it depends, how to employ, to the greatest possible advantage, the force of animal agents."

Dr. Haughton believes that he has found the proper form of this function, by means of experiments, and sums it up in what he calls the *Law of Fatigue*, which he thus expresses:—

The product of the total work done by the rate of work is constant, at the time when fatigue stops the work.

If W denote the total work done, the law of fatigue gives us—

$$W\frac{dW}{dt} = \text{const.}$$

or

$$\frac{W^2}{T} = \text{const.} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The experiments made by Dr. Haughton from 1875 to 1880 consisted chiefly in lifting or holding various weights by means of the arms; the law of fatigue giving, in each case, an appropriate equation, with which the results of the experiments were compared. When the experiments consisted in raising weights on the outstretched arms, at fixed rates, the law of fatigue gave the following expression—

$$(w + a)^2 n = A \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where w, n, are the weight held in the hand, and the number of times it is lifted, A is a constant to be determined by experiment, and a another constant depending on the weight of the limb and its appendages.

The equation (2) represents a cubical hyperbola.

The *useful work* done is represented by the equation—

$$w\,n = \frac{A\,w}{(w + a)^2} \quad . \quad . \quad . \quad . \quad . \quad (3)$$

This denotes a cuspidal cubic, and the *useful* work is a maximum, when $w = a$, or the weight used is equal to the constant depending on the weight of the limb and its appendages.

When the weights were lowered as well as raised at fixed rates, and no rest at all permitted, the law of fatigue became—

$$\frac{n(1 + \beta^2 t^2)}{t} = A \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where n, t, are the number and time of lift, A is a constant depending on experiment, and β is a constant involving the time of lift (τ) at which the *maximum* work is done.

Equation (4) denotes a cuspidal cubic.

When the weights are held on the palms of the outstretched hands, until the experiment is stopped by fatigue, the law becomes—

$$(w + a)^2 t = A \quad . \quad . \quad . \quad . \quad . \quad (5)$$

where t is the whole time of holding out.

This equation denotes a cubical hyperbola.

The *Law of Fatigue* seems, in itself, probable enough, but of course its real value depends on its agreement with the results of experiment.

If W denote the total work done and R the rate of work, the law becomes, simply—

$$W \times R = \text{const.} \quad . \quad . \quad . \quad . \quad . \quad (6)$$

If different limbs, or animals were used, each working in its own way, and under its own conditions, the *Law of Fatigue* would become—

$$WR = W_1 R_1 + W_2 R_2 + W_3 R_3 + \&c \quad . \quad (7)$$

and the problem for the engineer would be, so to arrange the work and rate of work of each agent employed, as to make the *useful work* a maximum, the work both useful and not useful, in all its parts, remaining subject to the conditions imposed by equation (7).

In using equation (5) in his concluding paper, detailing the results of experiments made on Dr. Alexander Macalister, Dr. Haughton treats a as an unknown quantity, and finds from all the observations its most probable value to be—

$$a = 5{\cdot}68 \text{ lbs.}$$

This result was compared with that of direct measurements made on Dr. Macalister himself, and indirect measurements made on the dead subject, from all of which Dr. Haughton concluded the value of a to be—

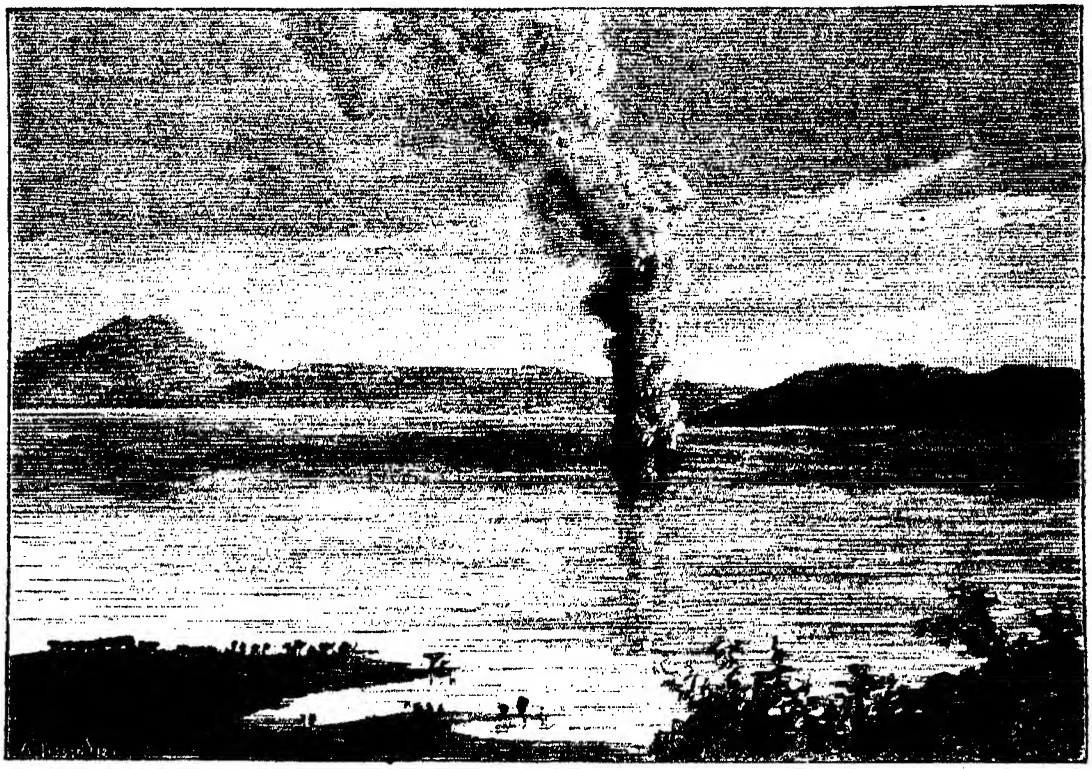
$a = 5{\cdot}56$ lbs. $\pm\ 0{\cdot}125$ (possible error).

This result agrees closely with that calculated from the law of fatigue.

It should be added that a proposal was made by Dr. Haughton to Dr. Macalister to make the experiment conclusive by direct amputation of his scapula, a course which he, unreasonably, objected to, as he draws the line of "vivisection" at frogs.

A LACUSTRINE VOLCANO

IN a recent number of *La Nature* further details, furnished by the French Consul of San Salvador, M. J. Laferrière, are given concerning the recent volcanic phenomenon in Lake Ilopango in that State. The accompanying illustration, from a photograph, will show the nature of the crater which has risen in the midst of the lake. Earthquakes were felt in San Salvador in the first half of January of this year; there were three strong shocks, less violent, however, than those of 1876. These earthquakes had their centre in the vicinity of Lake Ilopango, in the midst of which rose three volcanic openings connected with each other. This new crater, which, seen from a distance as in the illustration, appears a small islet, rises above the surface of the water, however, about twenty metres. An attempt was made to approach it in a boat, but the waters were all in a state of ebullition from contact with the burning rock, and gave off torrents of steam. An abundant column of smoke rose in the air, assuming the aspect of an immense cloud, which was seen from a great distance, and formed an imposing spectacle. The phenomenon was preceded by an exceptional rising of the lake, increased by the abundant winter rains. According to an old tradition the Spaniards maintain that when the lake rises earthquakes are to be feared. Formerly, also, it was the custom to dig trenches to facilitate the escape of the waters. This practice was followed without intermission for a century, and volcanic phenomena did not appear during all that time. The present phenomena seem to justify this tradition.



Aspect of the Volcano in Lake Ilopango. (From a Photograph.)

If it is difficult to explain the fact it is still interesting to remember that a great number of volcanoes are submarine, that others are found for the most part in islands or in maritime regions, and that water may be one of the feeders of volcanic fires. Lake Ilopango, also known as Lake Cojutepec, is, according to M. Laferrière, a sunk crater. It is in the volcanic line, and it is a general fact in Central America that lakes alternate with volcanic cones. The water of this lake is brackish, very bitter, and almost viscous. It gives off sometimes, here and there, bubbles of sulphohydric acid gas. The lake is about 12 kilometres long by 16 broad; the depth is unknown. It is about 12 kilometres from the city of San Salvador. The Consul of France in Guatemala, M. de Thiersant, states that Lake Ilopango has now a temperature of 38° C. on its shore, and is in complete ebullition round the volcano. All the fishes are cooked and float upon the surface, with a great number of shellfish and other aquatic animals. The volcano continues to rise, and the level of the lake is being gradually lowered.

NOTES

THE candidates whose names we gave in a recent number (vol. xxi. p. 616) were elected Fellows of the Royal Society at the meeting of last Thursday. They are:—Dr. Clifford Allbutt, Prof. J. Attfield, Mr. H. E. Blanford, the Rev. W. H. Dallinger, Mr. Thiselton Dyer, Lieut.-Col. Godwin-Austen, the Bishop of Limerick, Prof. D. E. Hughes, Mr. H. M. Jeffery,

Prof. F. M'Coy, Mr. J. F. Moulton, Prof. C. Niven, Dr. J. Rae, Prof. J. E. Reynolds, Dr. W. A. Tilden.

In the last number of the Berlin Chemical Society's *Journal* Prof. V. Meyer announces that he has been able to determine the density of iodine vapour at a considerably higher temperature than before, and that he has obtained values closely approximating to those required on the assumption that the gas then consists of *monatomic* iodine molecules. He proposes to extend his observations, if possible, to still higher temperatures, in order to ascertain whether the dissociation can be carried further; for this purpose he proposes to employ the recently described oil furnace of Deville and Troost, which is capable of fusing porcelain, and he hopes to be able to make use of vessels of graphite if those of porcelain are not sufficiently refractory.

From a copy of some correspondence which has passed between Sir Joseph Whitworth and Lord Beaconsfield, we see that Sir Joseph wrote to his Lordship on February 21, calling his Lordship's attention to what he had done so far back as twenty-four years since to the improvement of rifled arms. "By means of elaborate and careful experiments I obtained facts, and established certain laws, both with regard to artillery and small arms. These laws have never been invalidated. Some, though denied and disregarded at the time, are now accepted without question by all who have studied the subject, not only in this country but abroad; while others, equally important, have not yet been acted upon." Sir Joseph, after stating that he is anxious to point out the very unsatisfactory nature of the present system of determining questions, or rather of advising the responsible Minister on subjects which require a knowledge of mechanics and metallurgy, says: "I believe I am not doing any injustice to the officer or officers who have, or who have had, for years past, to advise the Secretary of State for War in these matters, when I say they have no such knowledge—they cannot have it. The very fact that they are able and distinguished soldiers precludes it. Nor, as far as I am aware, has the possession of mechanical knowledge, or of what I may term a mechanical instinct, any bearing on their selection for a post for which administrative ability is necessarily a first qualification. Further, the War Office has no such skilled technical advisers as the Admiralty has in naval architects and naval engineers. It is to this that I attribute the deficiency in our artillery and small arms. Instead of being, as we might be, in advance of other nations, it is a question whether we are on a level with some of them." Sir Joseph then asks the favour of an interview, in order to bring this matter more clearly before Lord Beaconsfield, who received the request very favourably. Unfortunately, before Sir Joseph was able to carry out his disinterested intentions, he was compelled to leave the country on account of his health.

A new skating surface called "crystal ice" has been invented by Dr. Calantarients of Scarborough. Considering that after all ice is merely a crystalline substance, and that there is no lack of substances that are crystalline at ordinary temperatures, Dr. Calantarients experimented with a variety of salts, and after a time succeeded in making a mixture consisting mainly of carbonate and sulphate of soda, which, when laid as a floor by his plan, can be skated on with ordinary ice-skates; the resistance of the surface is just equal to that of ice, it looks like ice, and indeed when it has been skated on, and got "cut up" a little the deception is quite astonishing; a small experimental floor has been laid in the skating rink at Prince's, and has proved so successful that no doubt a large floor will be laid there or at some other convenient place in the autumn. This floor will obviously have great advantages, both over artificial ice floors, which are very expensive indeed, and over floors for roller-skating. The surface can at any time be made smooth again by steaming with an apparatus for the purpose, and the floor itself when once laid will last for many years. It is interesting to observe that the mixture of salts used contains about 60 per cent. of water of crystallisation, so that after all the floor consists chiefly of solidified water.

Members of the General Committee and others who have not yet paid their subscriptions to the Clifford Testimonial Fund are requested to forward them to Messrs. Robarts, Lubbock, and Co., or to either of the honorary secretaries, Dr. Corfield, No. 10, Bolton Row, Mayfair, W., and Dr. Lee, No. 6, Savile Row, W.

In our next number we shall give the first instalment of a paper by Drs. De La Rue and H. W. Müller, on some of their most recent Experimental Researches in Electricity. The second instalment of this paper will be accompanied by a fine steel plate illustrating the experiments, kindly furnished to us by Dr. De La Rue.

We understand that a most interesting entomological problem has been solved. The singular aquatic animal originally described by Latreille as a crustacean under the name *Prosopistoma*, and which the French entomologists have affirmed to be the aquatic condition of an insect of the family *Ephemeridæ*, has been traced through all its transformations by M. Vayssière, and the result is such as to entirely confirm their belief.

The Annual Visitation of the Royal Observatory was made on Saturday, when the Astronomer-Royal presented his usual report.

The first of the Davis Lectures for 1880, on "Teeth," by Prof. Flower, was given in the lecture-room in the Zoological Society's Gardens, in the Regent's Park, on Thursday last week. The other lectures are as follows, the hour of lecture being 5 p.m.:—June 10, "Cats," by Prof. Mivart, F.R.S.; June 17, "Tadpoles," by Prof. Parker, F.R.S.; June 24, "Hawks and Hawking," by J. E. Harting, F.Z.S.; July 1, "Cuttle-fishes and Squids," by Prof. Huxley, F.R.S.; July 8, "Waterfowl," by P. L. Sclater, F.R.S.; July 15, "Birds," by W. A. Forbes, F.Z.S. These lectures will be free to Fellows of the Society and their friends, and to other visitors to the Gardens.

As we announced last week, the annual meeting of the Helvetic Society of Natural Science will be held at Brieg (Canton Valais), at the foot of the Simplon, on September 12 to 15. The great building of the college and the palace of Baron Stockalper are at the disposal of the Society. The committee speak in glowing terms of the various attractions which will be found in this locality by geologists, mineralogists, and entomologists, the "generous wine of Valais" being not the least among the attractions promised to botanists.

The twelfth meeting of the Scandinavian Naturalists and Physicians will take place at Stockholm on July 7 to 14 inclusive. A numerous attendance is expected from Denmark and Norway, as well as from other countries.

A large German Horticultural Exhibition is planned for the summer of 1882. It will be held at Bremen in connection with the twenty-fifth anniversary of the foundation of the Horticultural Society of that city.

It is believed that the engineers of the St. Gothard Tunnel will be able to overcome the difficulty arising from the threatened collapse of the passage in the part known as the "Windy Stretch." According to Prof. Colladon, the strata in this section are composed of a calcareous aluminous schist, which has a great affinity for moisture, and swells enormously on exposure to the air. If a tunnel were made through Mont Blanc, 3,000 metres of similar material would have to be pierced and vaulted.

M. Bresse has been elected to fill the place vacated by the death of General Morin in the Section of Mechanics of the Paris Academy of Sciences.

The Vesuvius railway was opened on the 6th inst. with much ceremony. It was found to work with perfect satisfaction.

An experiment with Jamin's electric candle was made on a large scale at the works of the Compagnie Générale d'Electricité, 67, Avenue du Marine, Paris, on June 3. About 1,900 people had been invited, amongst them the principal authorities of the French Republic. The light was found steady, but it remains to be seen whether the expense is smaller than with other systems, and the apparatus can work during a series of days. The candles are moved by a combination analogous to Wild's patent. The weight of wire utilised for each of these frames is 600 to 700 grammes, which shows a length of about 80 metres. M. Jamin wants tension for working his candles, and his Gramme machines rotated with a very great velocity. The scene was very picturesque and the general impression was good, although not enthusiastic, as has been reported in several political papers.

The Swiss Naturalists Association have decided to erect the Meteorological Observatory, the establishment of which was recommended to them by the International Meteorological Congress which met at Rome last year, upon the Säntis Mountain, in the canton of Appenzell. This peak is better adapted for the purposes of meteorological observation than any other one in Switzerland, on account of its comparatively isolated position. The observatory will cost about 320*l.*, besides which 360*l.* will be spent annually for its maintenance and staff.

Mr. G. H. Kinahan writes us that a wooden hut has been discovered lately under sixteen feet of bog by Thos. Plunkett, M.R.I.A., of Enniskillen. It is remarkable that this structure is at the same depth as the similar structure found at Drumkelin, and described by Wilde in the Catalogue of the Royal Irish Academy.

A large crowd is attracted every night to the Palais de l'Industrie, Paris, where are burning regularly 400 Jablockhoff lights, on the occasion of the Exposition des Beaux Arts, a floral exhibition having taken place in the nave from June 1 to 10, the scene in the nave surpassing description.

Electric light experiments on a large scale will be conducted with Wild candles at the Universal Exhibition of Melun. The gardens will be opened every night and lighted by electricity.

An international exhibition was opened at Brussels on June 1 by the king. It is a private speculation, which must not be confounded with the national exhibition which will be opened on June 19, and is the only official display in the capital of Belgium.

M. Marche has invented in Paris a new telephone, which he calls electrophone, and which works with an induction coil. The induction current is sent from a distance which is said to be very large, and the hearing is said to be satisfactory.

M. Cailletet, a telegraphist of Lille (Nord), discovered a new method of rotating the electro-magnetic gyroscope with any induction coil. It is to employ the thin wire as an inductor, and the thick one for sending the induction current to the coil.

A prospecting party, despatched by the Queensland Government, is stated to have discovered a very rich gold-field on the Sefton River in the north of the colony. An examination of the country along the east coast of Cape York Peninsula has not, however, proved successful.

It is stated that at Wickham, about 100 miles south of Sydney, New South Wales, two surface bands of metallic stone of considerable width have just been discovered. On analysis it is found that there is a large amount of gold and silver in one of these, while the other contains over 60 per cent. of iron with traces only of gold. A large and enormously valuable diamond is also said to have been discovered in the same locality.

The Naples correspondent of the *Daily News* states that twelve miles south of Sciacca, on the coast of Sicily, an exceedingly rich bank of corals has been discovered, which is even more important than the one found in 1876 in the same waters.

Mr. David Bogue has now at press and will shortly publish a new work, viz., "Birds, Fishes, and Cetacea of Belfast Lough," by Mr. R. Lloyd Patterson, vice-president of Belfast Natural History Society, and president of Belfast Chamber of Commerce, son of the late Robert Patterson, F.R.S. The book will form an interesting and valuable addition to this branch of natural history.

A terrible forest fire took place in the Harz Mountains on May 27 last. The whole forest of the Great Jügelsberg, near Goslar, is destroyed.

The forty-fourth general meeting of the Saxon and Thuringian Natural History Society took place at Nordhausen on May 18 and 19 last. The Society numbers between 300 and 400 members.

The nights of May 18 and 19 were fatal to almost all vineyards on the banks of the Rhine and its tributaries. The young shoots on most of the vines were killed by the frost, which was intense.

An interesting novelty in the German book-market is "Upilio Faimali, Memoiren eines Thierbändigers," collected by Paul Mantegazza. It is published by Winter, of Heidelberg. Faimali was one of the few tamers of wild animals who gained universal reputation. The book contains interesting narratives of his numerous adventures with various beasts.

On May 11 last the statue of the late M. Quetelet was unveiled in the gardens of the Brussels Academy buildings. He is represented in a sitting posture, his left hand rests upon a large celestial globe, and he holds a pen in his right. The expressive features are said to be an excellent likeness.

A curious survival of mediæval superstition has cropped up in a rumour which obtains credence in the West of England, that Balmain's luminous paint is prepared with *human fat*, in order to give it its phosphorescent properties!

On the Schleswig coast in the Little Belt the establishment of oyster beds is engaging the active attention of the authorities. One million and a half of small oysters have been "sown out" between the Gjenner Bay and the Danish frontier near Heilsminde.

OUR ASTRONOMICAL COLUMN

Winnecke's Comet.—In No. 2,314 of the *Astronomische Nachrichten* Prof. v. Oppolzer has a note of more than ordinary interest on the motion of this body as investigated by his own calculations. He states that it results from his computation of the perturbations with the object of connecting the three appearances of 1858, 1869, and 1875 that a satisfactory agreement cannot be found without one of two hypotheses; either the mass of Jupiter must be diminished to $\frac{1}{1051}$, or there is a necessity of admitting the existence of a similar extraordinary influence upon the motion of this comet to that first pointed out by Encke in the motion of the comet which bears his name. Prof. Oppolzer finds an acceleration in the mean daily sidereal motion of $0''\cdot01439$ after one revolution, a result which, he remarks, is in close accordance with his earlier one, deduced by a provisional calculation of

the perturbations, from the observations made at the comet's appearance in the summer of 1819. He infers from his researches upon Winnecke's comet a value for Encke's force designated by U, differing little from that assigned by Encke from his discussion of the motion of his comet, the more satisfactory considering that much latitude must be allowed in this direction. He further observes that with U = $\frac{1}{500}$ the effect upon the motion of Faye's comet would be so small that it is necessarily mixed up with uncertainty in the values of the perturbations; it will be remembered that Prof. Axel-Möller, who has laboured so admirably to follow up with every precision the motion of Faye's comet, has not, since his computations assumed their present refined form, been able to detect any abnormal effect upon it.

With regard to a diminution in the mass of Jupiter it is to be remarked that all the newer reliable determinations have confirmed the value deduced by Bessel from the elongations of the satellites, including that inferred by Prof. Krueger from the perturbations of Themis, and that which Dr. Axel-Möller has found from his researches on the motion of Faye's comet. Such diminution, therefore, appears inadmissible.

The Imperial Observatory, Strassburg.—In a communication to the *Astronomisches Gesellschaft* Prof. Winnecke has given details of the construction and instrumental equipment of this new establishment, which we cannot doubt, under his skilful and energetic direction, is destined to take its place amongst the most prominent of astronomical institutions. The principal instruments are—(1) the meridian circle, with object-glass of 6·4 inches aperture, which has been constructed by Repsold and was completed several years since; (2) the alt-azimuth, of 5·35 inches aperture and 4·9 feet focal length, also by Repsold; (3) the refractor, of 19·2 inches aperture and 23 feet focal length, by Merz, but mounted by Repsold, the object-glass being found to be of great excellence; (4) an "orbit-sweeper," constructed according to the design of Sir George Airy, as explained in the *Monthly Notices* of the Royal Astronomical Society, vol. xxi. p. 158; this is, so far as we know, the only instrument of the kind yet mounted, and has been used for some time by Prof. Winnecke in the provisional observatory at Strassburg; the aperture of the object-glass is 6·4 inches, which is not greater than it is essential to provide for the advantageous use of the peculiar mounting. We may hear of the application of the "orbit-sweeper" to the search (which it is not too soon to commence) for the comet of 1812, and later on for Olbers' comet of 1815, neither of which bodies will admit of accurate prediction. A plan of the buildings and grounds accompanies Prof. Winnecke's notice in the *Vierteljahrsschrift*.

The Companion of Sirius.—Mr. Burnham publishes mean results of numerous measures of the small companion of Sirius made with the 18-inch refractor at Chicago in the years 1877–80. We subjoin them with the errors indicated for Prof. Auwers' ephemeris in his *Untersuchungen über veränderliche Eigenbewegungen*:—

Epoch.	Position.	Error of ephemeris.	Distance.	Error of ephemeris.
1878·01	52°·4	+6°·0	10″·83	−0″·78
1879·13	50·7	+5·5	10·44	−0·77
1880·11	48·3	+5·7	10·00	−0·72

METEOROLOGICAL NOTES

Among the interesting papers which appear in the *Annales du Bureau Central Météorologique de France* for 1878 there is one by Prof. Hildebrandsson, of peculiar value, On the Freezing and Breaking-up of the Ice on the Lakes, the Epochs of Vegetation, and the Migration of Birds in Sweden, based on the observations made by a numerous staff of observers scattered over the country. The paper is illustrated by a diagram showing the seasonal distribution of temperature for ten of the more typical climates of Sweden, and by twelve maps indicating the geographical distribution of the physical and biological phenomena under discussion. Since the lakes of Sweden, which occupy a twelfth part of its entire superficies, exert powerful and diverse influences on plant and animal life, according as they are frozen or open, special attention has been directed to their examination. The results show that while the lakes in the extreme south are covered with ice on an average of ninety days in the year, those in the extreme north are 230 days bound with ice. The average date of the freezing of the lakes in the north is October 10, whereas in the south this does not take place till December 10. On the other hand, the ice breaks up in the southern lakes on April 1, but in the north not until the first week of June. The maps show the decided manner in which the curves are deflected and modified by such extensive sheets of water as are presented by Lakes Wener, Wetter, and Maelar, by height above the sea, and by the Atlantic in different seasons. During the freezing of the lakes the south-west winds of the Atlantic attain a maximum force and frequency, and under this influence the high lakes to westward of the head of the Gulf of Bothnia do not freeze till November 30, or six weeks later than the lakes in the same latitude near Haparanda. On the contrary, at the time of the breaking-up of the ice in spring, easterly winds are prevalent, and the ice on the lakes near the head of the Gulf of Bothnia breaks up four weeks earlier than that of the more elevated lakes to westward. An interesting examination is made of the dates of the breaking-up of the ice on Lake Maelar at Westerås from 1712 to 1871, and from a comparison of the averages of each of the ten-year periods it is seen that the earliest was April 14 for the decade 1722-31, and the latest, May 5, for 1802-11. Whilst the results for these 160 years indicate considerable fluctuations, they give no countenance to the idea that any permanent change has taken place in the climate of Sweden. Three maps show the number of days in which the plants that flower in the extreme south in April, and those in May, come successively into bloom, and the leafing of trees occurs at different places on advancing northward. As regards the plants which come into bloom in the south in April, their time of flowering is forty-five days later at the head of the Gulf of Bothnia, and sixty days later in the elevated districts to westward, but as regards the plants which bloom in the south in May, the times are only twenty-five and thirty-five days. The curves of the May flowers are closely coincident with the curves representing the breaking-up of the ice of the lakes. The time taken for the advance northward from the south to the head of the Gulf of Bothnia is twenty-three days for the leafing of trees and the flowers of May, whereas the time taken by the April flowers is forty-three days. The curves showing the times of arrival of four of the more marked of the migratory birds differ much from each other. The lark arrives in the south on March 1, and in the north on May 1, and the arrangement of the curves of arrival closely agrees with the curves showing the breaking-up of the ice of the lakes but a month earlier. As regards however the wild goose, the cuckoo, and the woodcock, the curves showing their arrival assume a different form, and point to an intimate connection subsisting between the arrivals and the temperature of the place at which they arrive.

To mark the high value they set on carefully-made observations, the Council of the Scientific Association of France have awarded medals to Lieut. Pouvreau, serving on the line from Havre to New York, Lieut. Benoît, of the *Yang-Tsé*, plying between Marseilles and Shanghai, and Captain Corenwinder, of the *Grenadier*, Dunkirk, for the meteorological observations made by them, these comprising, in addition to the usual observations, numerous and elaborate notes on whirlwinds and other special phenomena. At the same time a medal was awarded to M. Vidal, schoolmaster at Fraisse, Hérault, for a peculiarly interesting series of observations made by him during the past fifteen years, regularly in winter as well as in summer, at a height of 3,150 feet above the sea. M. Vidal has also, from his wide and varied knowledge of the natural sciences, rendered effective service to scientific men in their excursions into the higher districts of that part of France.

Prof. Fornioni has recently described to the Istituto Lombardo (*Rendiconti*, vol. xiii. fasc. 3) a simple nefodoscope, or instrument for measuring the direction of motion of clouds (the instrument of the kind known as that of Braun being thought expensive and inconvenient to use). It consists of a flat compass case with pivoted needle, above which is fixed horizontally a plane mirror occupying the whole of the case. On the surface of the glass are drawn diagonal lines corresponding to the rise of winds. The amalgam is removed in a narrow arc extending from north to north-west, so that the end of the needle may be seen for the purpose of orientation, and this transparent arc is graduated. A rod with terminal eye, freely pivoted on the edge of the case, completes the instrument. When the direction of a given cloud is to be determined, the nefodoscope is placed in a horizontal plane and properly oriented. The rod

is then moved to such a position that the observer's eye sees three points in a straight line, viz., the eye of the rod, the centre of the mirror, and the reflected image of a selected point of the cloud. The direction of the displacement which the latter undergoes after a time, proportional to the velocity of the cloud and inversely as its distance, is the required direction.

THE Report of the Royal Society of Tasmania for 1878 includes the tri-daily meteorological observations made at Hobart Town by Mr. Francis Abbott, so long an enthusiastic observer there, together with the annual abstract of his observations, and also an annual abstract of observations made by Mr. W. E. Shoobridge at New Norfolk, situated about fifteen miles from Hobart Town, higher up the Derwent. Observations were formerly made at Port Arthur, Swansea, Swan Island, and Kent's Group, viz., from 1861 to 1866, but at present Hobart Town and New Norfolk appear to be the only meteorological stations in the colony, the observations at Hobart Town dating from 1841, and those at New Norfolk from 1874. Mr. Abbott prints also his daily observations made at 10.33 P.M. in connection with Gen. Myer's international synchronous observations, the importance of which we have several times had occasion to refer to in describing the United States weather maps. The regular hours of observation are 7.30 A.M. and 4.30 P.M., these hours having been adopted since 1876, as stated in the Report, with the view of assimilating the records more closely with those of stations in Europe, America, &c., in order to co-operate in a system of international meteorology. These hours have not been happily chosen for general meteorological purposes, particularly since it is the practice to adopt as the mean temperatures of the separate months simply the mean of the observations at the above hours, which, whilst only very slightly below the true mean during the winter months, are from 1°·5 to 2°·8 too high for the four warmest months of the year.

PHYSICAL NOTES

AT the last meeting of the Physical Society of Paris some new and curious experiments upon the so-called magic mirrors of Japan were shown by M. Duboscq and discoursed upon by M. Bertin. Mirrors having a sufficiently true surface to give a fairly good virtual image of an object held near to them may yet be very irregular in the actual curvature of the surface and produce a very irregular real image of a luminous point reflected by the mirror upon a screen. If such a mirror be warmed the thinner portions change their curvature, becoming flatter, and yield dark corresponding patches in the disk of reflected light. A mirror which gives very imperfect effects when cold will give very good ones when heated. If, by means of a condensing pump, a uniform pressure is exerted against the back of the mirror, the thinner portions are more affected than the thick portions, and therefore, as viewed from the front, become less concave than the rest of the surface, the result upon the reflected beam being that the pattern of the thicker parts comes out bright on the darker ground of the image. Lastly, if a mirror be *cast* upon the face of the original mirror, and then polished, it will when warmed become a "magic" mirror, though when cold it yields only a uniformly illuminated disk upon the screen. This last experiment alone suffices to show that the cause of the reputed magical property is to be sought not in any difference of reflective power in different parts of the surface, but in slight differences of curvature of the surface.

A NEW zinc-carbon battery, the patent of Mr. R. Anderson, is announced. The exciting liquid is a mixture of hydrochloric acid, bichromate of potash, and of certain other "salts" in a mixture, for the composition of which Mr. Anderson claims the protection of the patent. The battery may be used either with or without a porous cell. It is stated that the E.M.F. of this battery is as high as 2·15 volts, that it is remarkably free from local action and internal resistance, and that it is very constant, one cell having twelve square inches of effective surface of the zinc, giving for seventy hours a constant current.

MR. A. A. MICHELSON, of the U.S. Navy, has communicated to the New York Academy of Sciences some interesting observations upon the diffraction and polarisation effects produced by passing light through a narrow slit. If a fine adjustable slit be narrowed down very greatly, the coloured diffraction fringes widen out until when the width of the slit is reduced to less than one-fiftieth of a millimetre, the central space only is seen, and appears of a faint bluish tint. Moreover, the light so transmitted exhibits traces of polarisation when regarded through a Nicol prism. If the slit is still further narrowed, the depth of the tint and the amount of polarisation increase, until, when a width of only one-thousandth of a millimetre is reached, the colour becomes a deep violet and is perfectly polarised. In this experiment the Nicol prism may be used either as polariser or as analyser. Slits of iron, brass, and obsidian produce identical results, though with the latter material, which can probably be more finely worked, the effects are the most pronounced. The polarisation is in a plane at right angles to the length of the slit. The phenomenon is best observed by using direct sunlight, placing the slit as near the eye as possible, and analysing with a double-image prism, thus enabling the delicate changes of tint to be observed by comparison. The possible explanation that the light which thus comes through the slit is reflected at its edges accords with the direction of the plane of polarisation; but there remains the difficulty that these effects should take place with all widths of slit and vary with the nature of the materials. One important point is that a slit of this degree of fineness admits the shorter waves of light more freely than the longer waves.

LORD RAYLEIGH showed a curious experiment in colour-combinations to the Physical Society, when he produced a yellow liquid by mixing a blue solution of litmus with a red solution of bichromate of potash. We recollect a kindred experiment which is even more curious, namely, the production of white by the mixture of crimson and green. An aqueous solution of cuprous chloride and a solution of rosaniline acetate in amylic alcohol are placed in a bottle in certain relative quantities. The crimson solution floats upon the green solution. But when shaken up together both colours disappear, and the mixture is simply a turbid greyish white.

MR. PREECE'S new microphone or telephone transmitter has at least the merit that it surpasses all others for simplicity. A very thin wire stretched between two points forms part of a circuit containing a Bell telephone and a small battery. When it is set vibrating by sounds, the vibrations, by varying the strain to which it is subjected, alter its conductivity, probably by producing alterations in its temperature.

M. OBALSKI describes a pretty magnetic curiosity to the Académie des Sciences. Two magnetic needles are hung vertically by fine threads, their unlike poles being opposite one another. Below them is a vessel containing water, its surface not quite touching the needles. They are hung so far apart as not to move towards one another. The level of the water is now quietly raised by letting a further quantity flow in from below. As soon as the water covers the lower ends of the needles they begin to approach one another, and when they are nearly immersed they rush together. The effect appears to be due to the fact that when the gravitation force downwards is partly counteracted by the upward hydrostatic force due to immersion, the magnetic force, being relatively greater, is able to assert itself.

THE phenomenon of luminosity of a (especially) negative electrode of small surface used in electrolysis of, *e.g.*, acidulated water, has been investigated by Prof. Colley of Kasan (*Jour. de Phys.*, May). Examining the light (which Slouguinoff found associated with an intermittence of the current) with a rotating mirror, he saw on a weakly luminous ground a multitude of bright star-like points, each appearing only an instant, and distributed without apparent regularity. The spectrum of the negative electrode was found to be composed of bright lines, determined both by the liquid and the substance of the electrode. Some physicists have thought that the electrode is considerably heated, and that the liquid round it assumes the spheroidal state, being separated by a layer of vapour. M. Colley finds that with a very strong current the electrode indeed becomes incandescent, and the liquid ceases to moisten it. He shows, however, that the illumination may be produced on an electrode quite cold, and he seeks the cause of production of vapour (of which he supposes the isolating layer to consist) in the high temperature of the liquid immediately surrounding the electrode (not in that of the electrode itself), heat being developed by reason of the small surface and small conductivity of a thin sheath of liquid. With a pile of 100 Bunsen couples, water containing 5 per cent. of sulphuric acid, and an electrode of 10 sq. mm. surface, 1·3 seconds would suffice to raise the layer next the electrode from 20° to 100° C. The sheath of gas

formed round the electrode may serve as germ for formation of a layer of vapours, and this being once formed, the discharges occur by sparks.

GEOGRAPHICAL NOTES

WE are delighted to find that our good neighbours, the French, will not be behind the rest of the scientific world in exploring the depths of the sea. A large Government steamer, the *Travailleur*, will be at Bayonne on the 15th of next month to undertake a dredging expedition along the Atlantic coasts of Spain, under the charge of Prof. Milne-Edwards and the Marquis de Folin. Dr. Gwyn Jeffreys and the Rev. Mr. Norman have been officially invited to take part in this expedition. The Dutch are also making arrangements for a dredging expedition in the West Indies.

FROM a note in the June number of the *American Naturalist* it seems extremely likely that the U.S. Senate will endorse the approval given to the Howgate Polar Expedition by the House of Representatives. The steamer *Gulnare*, 230 tons burden, is being fitted up, and will have a crew of fifteen officers and men. The observing party, which will be left at the station as near Lady Franklin Bay as possible, will consist of twenty-five men, including the necessary scientific corps. A house of wood is being fitted up for the men to winter in on the shores of Discovery Bay, and a steam launch will form part of the expedition. "In making this report the committee respectfully state and report that the object of the bill, as is shown by its terms, is to authorise a temporary station to be selected within the Arctic circle, for the purpose of making scientific discoveries, explorations, and observations, obtaining all possible facts and knowledge in relation to the magnetic currents of the earth, the influence of ice-floes therefrom upon the winds and seasons, and upon the currents of the ocean, as well as other matters incidental thereto, developing and discovering at the same time other and new whale-fisheries, now so material in many respects to this country. It is, again, the object of this bill that this expedition, having such scientific observations in view, shall be regularly made for a series of years under such restrictions of military discipline as will insure regularity and accuracy, and give the fullest possible return for the necessary expenditure; and again, in view of the fact that either the governments directly, or scientific corps under their authority, of Germany, Holland, Norway, Sweden, Austria, Denmark, and Russia, have concurrently agreed to establish similar stations, with like object, during the year 1880, it is believed that the interests and policy of our people concur in demanding that the United States should co-operate in the grand efforts to be thus made in the solution of the mysteries and secrets of the North Polar seas, upon which, in the opinion of scientists, depends so much that affects the health and wealth of the human race." This station will form one of the series of International Arctic Observatories to which we have already referred.

DURING the past year H.M.S. *Alert*, first under Sir G. S. Nares, and afterwards under Capt. Maclear, was engaged in very useful service on the west coast of South America, chiefly in examining the channels in about 50° S. lat. Trinidad Channel, which opens out a clear passage to the Pacific 160 miles north of Magellan Strait, has been carefully surveyed, together with its various ports and anchorages. This channel forms a valuable addition to our knowledge of these waters, as it will enable vessels bound westward to avoid the heavy sea often met with in the higher south latitude. Its southern shores are bounded by bold rugged mountains rising abruptly from the sea, and on the north side a low wooded country lies between the sea and the snow-clad mountains in the distance. The *Alert* also visited St. Felix and St. Ambrose Islands, which, owing to the depth of the soundings obtained, are thought to be unconnected with both the South American continent and the San Juan Fernandez group. Capt. Maclear describes St. Ambrose Island as volcanic, composed of lava in horizontal strata, intersected vertically by masses of basalt. Vegetation is scant, and the island is without water; though frequented by sea-birds, its sides are too steep and rugged for guano to collect. From the soundings it would seem that this, as well as the other islands, rises as an isolated mountain from a submarine plateau.

AT the meeting of the Paris Geographical Society of May 7 a Greek physician, Dr. Panagiotés Potagos, was introduced by MM. Ujfalvy and Duveyrier as one of the most extensive travellers of our time. M. Potagos, we are told, has since 1867, beginning at Tripoli in Asia Minor, visited Teheran, skirted the Paropamisus on his way to Medjid, Herat, Kandahar and Kabul; crossed the Hindu Kush by one of the most difficult passes, traversed Badakshan, Wakhan, and all Kashgaria, arriving at Hami in 1871. Thence he went to Ulussutai in the heart of Mongolia, returning to Hami, where all his notes and collections were destroyed, and he himself kept prisoner for more than a year. Thence continuing his journey, he reached Kulja, and returned to Europe by Semipalatinsk, Omsk, Moscow, and St. Petersburg. After staying at Salonica for two years, he went to Bombay and Peshawur, descended the Indus to Karachi, thence to Bunder-Abbas in Persia, crossed the mountains of Laristan, and made his way to Kabul, reaching India again by the Kurrum Valley, meeting Major Cavagnari on his way. From Bombay he went to East Africa, and penetrated into the interior farther than Schweinfurth. The principal sphere of his African journeys seems to have been in the region of the River Beré, which M. Deveyrier is of opinion is the Wellé of Schweinfurth, but which, according to M. Potagos, cannot be connected with the Aruwimi of Stanley, but rather with the basin of the Shari. The observations of M. Potagos are, however, too vague to be of much scientific value, unless, indeed, further details be forthcoming.

MR. LAURENCE OLIPHANT has lately returned to England from a journey of exploration on the eastern side of the River Jordan, and is, we believe, engaged in preparing for publication an account of the results of his investigations.

THE map of Equatorial Africa, on the scale of 15·8 miles to one inch, on which Mr. E. G. Ravenstein has for some time been engaged for the Geographical Society, is stated to be approaching completion, and it is expected that the lithographed sheets will be ready during the summer. An analytical catalogue of works on African travel and geography, including papers in periodicals, is being compiled at the same time.

MR. STANFORD has just published a fine new wall map of New Zealand, on the scale of seventeen miles to an inch. The whole of the coast line, together with the details of harbours and banks of these islands, has been carefully reduced from the most recent Admiralty Charts. The interior details of rivers and mountains, roads and railways, towns and villages, have been plotted in from the various Government surveys and partly from private sources. Although not over-crowded with names, it contains, besides the chief physical features, the names of all villages and other centres of population, together with the names of many places of interest, such as the geysers or hot springs and the boiling lakes of the North Island. The principal Maori tribal names are also given over the areas once occupied by them. The map is coloured to show the boundaries of the new administrative divisions, all of which are named. The large size, accuracy, and clearness of this map render it eminently useful for teaching purposes.

THE annual address of Chief Justice Daly, President of the American Geographical Society, on the Geographical Work of the World in 1878 and 1879, is as usual, remarkably comprehensive and well arranged; indeed it is the best summary of the subject we have seen.

L'Exploration of June 2 contains an interesting article on the various explorations of M. Paul Soleillet in Africa. There is also a map of the French possessions and factories on the coast of Guinea.

"ANGLO-CANADIAN" sends us the draught of a scheme for reaching the North Pole by balloon in comparatively few days, at a cost which must take the gas completely out of the elaborate and expensive scheme of Commander Cheyne. Our correspondent has patented a directable balloon, which he maintains is capable of being moved at a rapid rate in any direction. We need not enter into the details of his plan, which reads very glibly, but which we should like to see subjected to rigid scientific tests. The whole scheme is to cost only 2,000*l.*, including a steamer to be chartered to Spitzbergen to take the necessary compressed gas which "Anglo-Canadian" would use as fuel. We do not attach much importance to the attainment of the Pole, and should prefer to see any money that can be raised for Arctic exploration in this country devoted to the founding of one of those international series of Arctic observations from which England is conspicuously absent.

It may interest such of our readers as are conversant with the German language to know that in the course of the present month Dr. Ernst von Hesse Wartegg will deliver a lecture at the German Athenæum (93, Mortimer Street, W.), entitled "Das Leben der Beduinen." The secretary of the institution will furnish all particulars regarding exact date and admission to the lecture on application by letter.

After the example of the German and Austrian Alpine Clubs, a Bohemian Mountain Club is now in course of formation.

The authors of Sweden and Finnland have edited a festive paper, "Nordostpassagen," in honour of Prof. Nordenskjöld's return, which deserves high commendation, both with regard to text and illustrations. It is published by C. E. Fritze, of Stockholm.

In a letter from M. Berlioux, read at the Paris Academy of Sciences on May 31, the writer attempts to prove from the last expedition of Dr. Rohlfs in the Eastern Sahara the marvellous correctness of Ptolemy's Tables.

It is stated that Col. Gordon, who has resigned his post on the staff of Lord Ripon, is to proceed to Zanzibar to join the Belgian African exploring expedition.

The question of the speedy completion of the Ordnance Survey came up in the House of Commons last Friday, when there was an almost unanimous consensus of opinion that Government ought at once to advance as much money as was necessary to complete the work. The reply of Mr. Adam and Mr. Gladstone was virtually a *non possumus*. It was not so much the difficulty of advancing the money as of obtaining the necessary amount of skilled labour to carry on the work under pressure. At the present rate the survey cannot be completed for eighteen years.

DR. SIEMENS' NEWEST ELECTRICAL RESULTS

A PAPER was read on Thursday last before the Society of Telegraph Engineers by Dr. Siemens, F.R.S., upon "Recent Applications of the Dynamo-Electric Current to Metallurgy, Horticulture, and the Transmission of Power." The author first referred to the inaugural address which he had given before the Society on his election to his second presidency, wherein he drew attention to the applicability of the dynamo-electric current to purposes beyond the range of what electricity had theretofore been employed in effecting. On the present occasion he corroborated his statements by a reference to recent experimental results of his own.

The first part of the paper had reference to an electric furnace. This furnace consists of any ordinary crucible of plumbago or other highly refractory material, which is placed in a metallic jacket or outer casing, the intervening space being filled up with pounded charcoal or other bad conductor of heat. A hole is pierced through the bottom of the crucible for the admission of a rod of iron, platinum, or dense carbon, such as is used in electric illumination. The cover of the crucible is also pierced for the reception of the negative electrode, by preference a cylinder of compressed carbon of comparatively large dimensions. At the end of a beam supported at its centre is suspended the negative electrode by means of a strip of copper, or other good conductor of electricity, the other end of the beam being attached to a hollow cylinder of iron free to move vertically within a solenoid coil of wire, presenting a total resistance of about fifty units or ohms. By means of a sliding weight the preponderance of weight of the beam in the direction of the solenoid can be varied so as to balance the magnetic force with which the hollow iron cylinder is drawn into the coil. One end of the solenoid coil is connected with the positive, and the other with the negative pole of the electric arc, and, being a coil of high resistance, its attractive force on the iron cylinder is proportional to the electromotive force between the two electrodes, or, in other words, to the electrical resistance of the arc itself.

An automatic adjustment of the arc thus arises of great importance to the attainment of advantageous results in the process of electric fusion; without it the resistance of the arc would rapidly diminish with increase of temperature of the heated atmosphere within the crucible, and heat would be developed in the dynamo-electric machine to the prejudice of the electric furnace. The sudden sinking or change in electrical resistance of the material undergoing fusion would, on the other hand, cause sudden increase in the resistance of the arc, with a likelihood of its extinction, if such self-adjusting action did not take place.

Another important element of success in electric fusion consists in constituting the material to be fused the positive pole of the electric arc. It is well known that it is at the positive pole that the heat is principally developed, and fusion of the material constituting the positive pole takes place even before the crucible itself is heated up to the same degree. This principle of action is of course applicable only to the melting of metals and other electrical conductors, such as metallic oxides, which constitute the materials generally operated upon in metallurgical processes. In operating upon non-conductive earth or upon gases it becomes necessary to provide a non destructible positive pole, such as platinum or iridium, which may, however, undergo fusion and form a little pool at the bottom of the crucible.

In this electrical furnace some time, of course, is occupied to bring the temperature of the crucible itself up to a considerable degree, but it is surprising how rapidly an accumulation of heat takes place. In working with the modified medium-sized dynamo machine, capable of producing thirty-six webers of current with an expenditure of four horse-power, and which, if used for illuminating purposes, produces a light equal to 6,000 candles, I find that a crucible of about twenty centimetres in depth, immersed in a non-conductive material, is raised up to a white heat in less than half an hour, and the fusion of one kilogram of steel is effected within, say, another half-hour, successive fusions being effected in somewhat diminishing intervals of time. It is quite feasible to carry on this process upon a still larger scale by increasing the power of the dynamo-electric machine and the size of the crucibles.

It was shown by means of a calculation that this furnace utilises $\frac{1}{3}$ of the horse-power actually expended, and as the efficiency of a good steam-engine is $\frac{1}{5}$, that of the electric furnace is $\frac{1}{3} \times \frac{1}{5} = \frac{1}{15}$. Now as it takes theoretically 450 heat units to melt 1 lb. of steel, there will be required actually $450 \times 15 = 6{,}750$ units in working with the electric furnace, or about the heat-energy residing in a pound of ordinary coal. To melt a ton of steel in crucibles in the ordinary air-furnace as practised at Sheffield, $2\frac{1}{2}$ to 3 tons of best Durham coke are consumed. A ton of coal is consumed per ton of steel produced if the regenerative gas furnace is used for heating the crucibles, whilst to produce steel in large quantities on the open hearth of this furnace about 12 cwt. of coal per ton of steel suffice. The electric furnace may therefore be considered as economically superior to the ordinary air-furnace, and, barring some incidental losses not included in the calculation, is nearly equal to the regenerative gas-furnace as far as economy of fuel is concerned. In favour of the electric furnace is an almost unlimited temperature, easy application, a neutral atmosphere within the crucible, and the circumstance that the heat within the crucible is greater than that external to it, whereas in ordinary fusion the temperature of the crucible is higher than that of metal within.

On the occasion of reading the paper a pound of broken files was melted in a cold crucible by means of a current of 72 webers in fifteen minutes, and cast in a liquid state, a second casting being effected in eight minutes. These and other brilliant successes of the new apparatus were hailed with ringing cheers.

In the second portion of the paper, referring to electro-horticulture, the author explained the experiments by means of which he has come to the conclusion that electric light produces the colouring matter chlorophyll in the leaves of plants, that it aids their growth, counteracts the effects of night frosts, and promotes the setting and ripening of fruit in the open air. It appears, further, that, at all events for certain short periods, plants do not require a period of rest during the twenty-four hours, but make increased and vigorous progress if subjected during daytime to sunlight and to electric light at night. These observations on combined sun and electric light agree with those made by Dr. Schübeler of Christiania, who found as the result of continued experiment in the north of Europe, during an Arctic summer, that plants, when thus continuously growing, develop more brilliant flowers and larger and more aromatic fruit than when under the alternating influence of light and darkness. As Dr. Siemens has found that under the influence of electric light plants can sustain increased stove heat without collapsing, he is of opinion that forcing may be effected in an electric stove or enclosure containing an electric light, and that horticulturists may thus grow fruit of excellent aroma and flowers of great brilliancy without immediate solar aid. To test what

can be done practically the author has put down a steam-engine and boiler at his country residence near Tunbridge Wells, and intends to test the principles involved upon a working scale during the winter. The steam-engine which drives the dynamo-electric machine during the night for the purpose of giving light is to be employed during the day in transmitting power through an electric conductor to the farm for the purpose of carrying on small farming operations such as turnip, chaff, and wood-cutting, &c. Another interesting question which Dr. Siemens has set himself to answer is to determine which portion of the rays constituting white light is efficacious in producing chlorophyll, starch, and woody fibre, and which in effecting the ripening of fruit. For this purpose arrangements are in preparation to distribute the spectrum of a powerful electric light in a darkened chamber over a series of similar plants exposed *seriatim* to the actinic, light-giving, and thermal portions of the spectrum. Some experiments have been made with solar light in this direction, but no very conclusive results could be obtained, because the short periods of time during which the solar spectrum can be maintained steadily in the same place are so short that the effects produced upon vegetation have not been of a sufficiently decided character; whereas, with the aid of electric light, the same spectrum may be kept on steadily for a series of days without intermission. The author referred shortly to the lamp which he designed for this purpose, having a focus unchangeable in space, and without obstruction to the rays of light falling downward. There is no clockwork; the carbons are pressed forward either by their own weight or by the force of springs, the motion being checked by an abutment against which the carbon presses at the junction of its cylindrical with its conical portion. This is at a distance of ⅛ inch to ¼ inch from the arc centre, when the heat is sufficient to cause the gradual decomposition of the carbon, without being high enough to fuse or injure the metal abutment.

In the third portion of the paper the author refers to the application of electricity as a means of mechanical propulsion. He described the electric railway designed by Dr. Werner Siemens, of Berlin, and tried at a local exhibition held in that city. The rails were insulated from the earth by wooden sleepers, and were in electrical connection with a dynamo-electric machine worked by steam power at the station. A magneto-electric machine on the driving carriage was so fixed and connected with the axle of one pair of wheels as to give motion to the same, the driving axle being severed electrically by the introduction of an insulated washer. A current of electricity is thus passed along one rail to work the magneto-electric machine on the driving carriage, and back by the other rail to the stationary machine on the ground. The author anticipates a large application of the electric railway to adits in mines, to locomotives between neighbouring places, and to tunnels. In fact it is seriously contemplated to apply this system at the St. Gothard tunnel, where the large turbines are available which have been employed in the boring operations.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—In their latest-issued series of statutes for the University of Cambridge, the Commissioners maintain Easter as the boundary between the University Lent and Easter terms, and require three-fourths of each term to be kept by residence. The degree of Bachelor in Surgery is added to the list; but the permission to give degrees to peers and sons of peers who come to the University in youth is limited to the B.A. degree, and the University may prescribe for their examinations and residence by grace. Titular degrees in any of the seven faculties of Arts, Law, Medicine, Surgery, Science, Letters, or Music may be granted to foreigners of distinction and to British subjects who are of conspicuous merit, or who have done good service to the State or to the University. Complete honorary degrees, with right of voting, may be given to those who obtain some University office after residing three terms in the University.

The Demonstrator of Anatomy will superintend a class for Practical Histology during the next long vacation, beginning July 1; another class will be held for Human Osteology. The Cavendish Laboratory also will be open for practical work.

Notice has been given by the Board of Natural Science Studies that next June (1881) there will be a practical examination in all the subjects of the examination in the first part of the Natural Sciences Tripos.

The recent memorials concerning the academical encouragement of the higher education of women are to be considered and reported on by a syndicate consisting of the Vice-Chancellor, Drs. Bateson, Phear, Westcott, and E. C. Clark, Professors Cayley, Adams, Liveing, and Stuart, Messrs. G. F. Browne, Ferrers, E. W. Blore, R. Burn, H. Sidgwick, J. Peile, A. Austen-Leigh, and G. W. Prothero, to report before the end of Lent Term next.

The Sedgwick prize, given every third year for the best essay on some subject in geology or the kindred sciences, open to the competition of all graduates of the University who have resided sixty days during the twelvemonth preceding the day on which the essay must be sent in, has been awarded to Walter Keeping, Inceptor in Arts, of Christ's College. The subject of the essay is, "On the Fossils and Palæontological Affinities of the Neocomian Beds of Upware, Wicken, and Brickhill."

SIR JOHN LUBBOCK has been elected without opposition to represent London University in Parliament.

PROF. HENRICI, F.R.S., has been appointed to the Professorship of Applied Mathematics in University College, London.

GREAT importance has been given to the first session of the Superior Council of Instruction of France, composed of about fifty members, of whom forty have been nominated by the different classes of French teachers, from the Sorbonne to the humblest village school. A decree has granted to each of them a sum of 20 francs a day for the duration of the session, and travelling expenses. M. Jules Ferry opened the session by a speech in which he explained his views, and submitted to the new organisation a programme of reforms. This programme has been sent by the General Assembly to a special commission composed of fifty members appointed to report on it. M. Jules Simon has been appointed president of that commission. It is said that, although approving the general tendency of these reforms, the commission is resolved to protect Greek studies, which had been sacrificed in the Ministerial project. But it agrees to render the study of either the English or the German language an obligation from the admission to the school up to the end of the course of studies. The commission has held already three long sittings for determining these points. The discussion will be long in general sitting. For the first time in the history of France the University has her own parliament to deliberate on all the subjects relating to public instruction. None of these deliberations are to be binding on the Government. All the provisions of the laws are to be voted as formerly by the French Chamber of Deputies and Senate.

SCIENTIFIC SERIALS

THE *Bulletin of the Torrey Botanical Club* is now published in regular monthly parts, instead of at irregular intervals. The papers are of course chiefly of local interest, and that is especially the case with the three numbers which we have received for the current year, though now and then morphological notes by Mr. Meehan and others are of a wider scope. At all events the *Bulletin* gives us in this country a lively idea of the activity of botanical research on the other side of the Atlantic. Mr. W. R. Gerard gives a description and drawing of a fungus new to science, *Simblum rubescens*, belonging to the Phalloidei.

UNDER the new editorship of Mr. James Britten the *Journal of Botany* loses none of its interest. In addition to contributions to phyto-geography, and smaller articles of special interest to the workers in the critical botany of British plants, the following, which have appeared in recent numbers, may be mentioned as being of a wider scope:—Mr. J. G. Baker's Synopsis of the species of *Isoëtes*, a useful contribution to our knowledge of vascular cryptogams; a much-needed review of the British Characeæ (not yet completed), by H. and J. Groves; and the botany of the British Polar Expedition of 1875-6, by Mr. H. C. Hart, the naturalist to the expedition.

THE *Nuovo Giornale Botanico Italiano* continues to be supplied with good and useful papers in the various departments of botany. In the two numbers already published during the present year (vol. xii. Nos. 1 and 2) there are articles by several of the leading Italian botanists. The editor, Prof. Caruel, gives a list of fifty false genera or species of plants founded on teratological or pathological circumstances. In an article on the parasitism of fungi by A. Bertoloni, he divides the class of fungi into two great divisions, according to their mode of life. The

first are true parasites, the mycelium of which, living on the tissues of the host, frequently kills it; the second are false parasites (saprophytes), deriving their nourishment from vegetable substances in various stages of decomposition. The genus *Polyporus* he considers to belong to the first, *Agaricus* to the second of these classes. The common disease of the mulberry-tree he attributes to *Polyporus mori*, not to *Agaricus melleus*, as suggested by Piccone.—A. Mori discusses the old statement of Gasparrini, recently revived by Licopoli, that beneath the stomata of the leaves are cavities, to which Gasparrini gave the name *cistoma*, which are clothed by a continuation of the cuticle. His observations do not lead him to confirm this statement, but rather to the conclusion that the walls of the cavity beneath the stoma consist of ordinary cellulose.

In the number of the *Scottish Naturalist* for April is the commencement of a suggestive article by the Rev. A. Milroy on the value of the names of places in indicating the ancient surface-features of the country. He takes as an example the country on the banks of the Tay below Perth, and shows the light that is thrown by the Saxon and Celtic local names, not only on the ethnological history of the district, but also on the changes which have taken place in its physical features.

The American Naturalist, May, contains:—Edward Burgess, the structure and action of a butterfly's trunk.—J. S. Lippincott, the critics of evolution.—E. H. Yarnall, Hall's second Arctic expedition.—O. T. Mason, sketch of North American anthropology in 1879.—The editor's table, on the Academy of Natural Sciences, Philadelphia.—On the proposed exploration of the ruins of Mexico and Central America—Recent literature.—General notes.—Scientific news.

Journal of the Franklin Institute, May.—Naval architecture, by Mr. Haswell.—Table and diagram for determining the diameters of speed cones when connected by an open belt of constant length, by Mr. Klein.—Experiments with a steam cutter, by Mr. Isherwood.—Eye memory, by Mr. Leland.

SOCIETIES AND ACADEMIES

London

Royal Society, May 13.—"Notice of Further Experimental Researches on the Time Relations of the Excitatory Process in the Ventricle of the Heart of the Frog," by J. Burdon Sanderson, M.D., and F. J. M. Page, B.Sc.

The present paper is a continuation of one previously published by the authors (*Roy. Soc. Proc.*, xxvii. 410). The excitatory state, *i.e.*, the condition produced in any excitable structure, vegetable or animal, by excitation, is characterised (1) by the appearance of electromotive properties in the excited part which did not exist before excitation and cease to exist as soon as its effect is over; (2) by diminished excitability; (3) by the fact that it is propagated from the part first excited to contiguous parts at a rate which is different in different structures and in the same structure at different temperatures. These three conditions are important as being the only characteristics by which the hidden process of excitation constantly reveals itself. By means of the rheotome described by one of the authors, exact measurements have been made of the time relations of the above conditions. The results obtained by Engelmann (*Pflüg. Arch.*, xvii. 68) are then discussed. In forty-seven out of seventy-eight preparations of the ventricle of the frog made by this observer, the leading-off contact nearest the point of excitation became first negative, then positive to the other leading-off contact; in the remaining thirty-one the positive deflection was absent. In the case in which the deflection was of a double character (*Doppelschwankung*), the first phase began 0″·06 after excitation, and rapidly attained its maximum; the reversal of sign took place at 0″·26, and the contacts became equipotential at 0″·5. He estimated the rate of propagation at 50 mm. per second. It will be noticed that these researches of Engelmann refer exclusively to the first half second after excitation, and therefore correspond to what has been termed by the authors of the present paper "the initial phase," and that the "terminal phase" escaped the notice of Engelmann. The method employed in the investigation of the above phenomena, with the aid of the rheotome, is then briefly described. The heart was carefully maintained at a constant temperature by being placed on a lacquered brass box, through which flowed a stream of water at the desired temperature. The following table gives

Time after excitation, at which galvanometric circuit was opened, the period of closure being 0″·1 ...	0″·1	0″·2	0″·3	0″·4	0″·5	0″·6	0″·7	0″·8	0″·9	1″·0
Deflections	−42	−3	0	0	0	0	0	0	0	0
Time after excitation, at which galvanometric circuit was opened, the period of closure being 0″·1 ...	1″·1	1″·2	1″·3	1″·4	1″·5	1″·6	1″·7	1″·8	1″·9	2″·0
Deflections	0	0	0	0	0	+3	+30	+12	+1	0

the results obtained in a typical experiment at 10° C., with the ventricle of the frog. The preparation was led off at apex and base, and excited close to the apex. The deflections represent the relative changes of potential at the apex contact. The authors reiterate the statement contained in their previous paper, that the electrical effect of excitation manifests itself in two phases, an initial and a terminal one, which have opposite signs, and further conclude that these two phases are separated by a relatively prolonged state of equipotentiality of the two apex contacts. These statements agree with those of Engelmann as far as they relate to the same period; but as the whole of the phenomena recorded by him belong to the beginning of the first second, the commencement of the period of equipotentiality is regarded by him as the end of the excitatory effect; but to the authors the absence of galvanometric effect during this isoelectrical interval is the expression of the fact that both contacts are in the same degree of excitation. The proof that this period of equipotentiality is one of balanced activities is obtained by subjecting the two led-off surfaces to different temperatures. If the apex be warmed the deflections of the terminal phase are increased, and commence at an earlier period; if the apex be cooled they are diminished. This is illustrated by the following table:—

Time after excitation, at which the galvanometer circuit was closed	0″·2	0″·4	0″·6	0″·8	1″·0	1″·2	1″·4	1″·6	1″·8	2″·0
Preliminary observation before warming	−30	0	0	0	0	+ 5	+23	+20	+ 5	0
Immediately after warming	−24	+17	+30	+71	+95	+99	+63	+ 9	+ 5	0
12 seconds later...	−25	+ 5	+ 2	+ 9	+25	+55	+52	+ 6	+ 2	0
24 seconds later...	−29	0	0	0	+ 6	+14	+50	+ 9	+ 2	0
36 seconds later...	...	0	0	0	+ 2	+ 7	+34	+14	+ 5	0
48 seconds later...	...	0	0	0	0	+ 5	+24	+16	0	0

Slight injuries, such as those produced by an application of a minute quantity of 10 per cent. salt-solution, resemble those effected by slight warming. If the injury is more complete, such as is produced by touching the surface momentarily by a red hot wire, the isoelectrical interval is as it were filled up; large deflections in which the warmed surface appears to be positive being obtained throughout the whole of the excitatory period excepting the first tenth. This is seen in the following table:—

Time after excitation of opening of galvanometer circuit, the period of closure being 0″·18.	0″·2	0″·4	0″·6	0″·8	1″·0	1″·2	1″·4	1″·6	1″·8	2″·0
Deflection	+58·6	+85·3	+82·3	+75·0	+68·3	+62·3	+50·0	+31·8	+21·3	+4·1

As regards the period of diminished excitability, the experiments of Marey ("Physiol. Exp." ii. 1876, 85) are first discussed, some experiments are then given which establish—(1) That the duration of the period of diminished excitability agrees pretty closely with that of electrical activity, and (2) that it is similarly affected by changes of temperature.

The rate of propagation of the excitatory wave in a fresh preparation is about 130 mm. per second.

The facts above stated are consistent with the following theories:—1. Every excited part is negative to every unexcited part so long as the state of excitation lasts. 2. The local duration of the excitatory state, *i.e.* the time it lasts in each structural element, is measured by the time interval between the beginning of the initial and the beginning of the terminal phase of the variation. 3. When both contacts are at the same temperature and in all other respects under the same conditions, the local duration of the excitatory state is the same at both, consequently it begins and ends earlier at the leading off contact first excited than at the other, the initial and terminal differences expressing

themselves in the initial and terminal phases of the normal variation. 4. When one contact is warmer than the other the local duration of the excitatory state is less in the warmed than in the unwarmed surface. 5. If the surface near one contact is slightly injured, the local duration at the injured surface is diminished in the same way as when the temperature is increased, but if the injury is of such intensity as to destroy its surface, its most prominent effect is to diminish its electromotive activity.

In an appendix the authors briefly consider the results of slight inequalities produced by mechanical, chemical, or thermal conditions on the potential of the surface of the ventricle in the resting heart, and the influence of temperature on the excitability of the resting heart.

A full account of the experiments, the results of which were communicated to the Society, will be published in the *Journal of Physiology*.

May 27.—"On some Thermal Effects of Electric Currents," by William Henry Preece, General Post Office. Communicated by Prof. Stokes, Sec. R.S.

I have been engaged for some time past in experimenting on the thermal effects of electric currents, but the final results of those experiments are not sufficiently ripe at present to justify my bringing them before the Royal Society. I have, however, obtained one result which I believe to be sufficiently novel to justify a short preliminary note.

The most striking facts elicited by these experiments are:

1. The extreme rapidity with which thin wires acquire and lose their increased temperature.

2. The excessive sensibility to linear expansion which fine wires of high resistance evince.

Now as the rate of heating, and therefore of expansion and contraction, varies very nearly directly as the increment or decrement of the currents when these variations are very small, it occurred to me that if a long wire of small diameter and high resistance were attached to a sounding board or to the centre of a disk (such as one of those used for telephones and phonographs) and it formed part of a circuit conveying telephonic currents, sonorous vibrations ought to be reproduced.

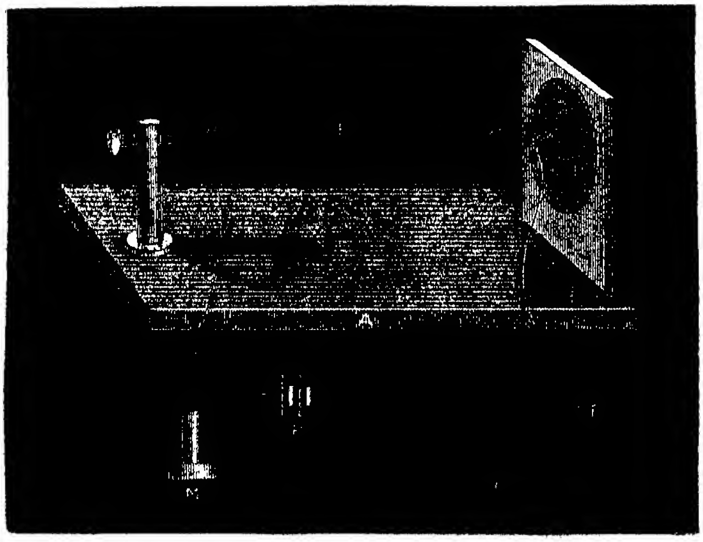
The sketch shows the arrangement of the apparatus used for the experiment.

A was a stout base of mahogany, on which a brass support C was attached so that it could slide and be fixed at any distance from D.

D was at first a disk of thin paper, and then of thin iron.

P was the wire experimented upon whose loose ends were connected to terminals on the wooden base, so as to be inserted in the circuit containing a microphone transmitter M and a battery B of six bichromate of potash cells in another room out of hearing.

A platinum wire of 0·003 inch diameter and 6 inches long from p to p' was first used, and the sonorous effects were most marked and encouraging when the microphone transmitter M



was spoken into. The articulation, though muffled, was clear, and words could easily be heard.

1. Experiments were first made to determine the length which gave the loudest sound and the clearest articulation, and, after repeated trials with every variation of length from 1 inch to 6 feet, it was found that a wire 6 inches long gave the maximum effect.

2. Experiments were then made to determine the diameter of the wire that gave the best effect, and after repeated trials with every gauge drawn from 0·0005 inch to 0·005 inch, it was found that wire of the diameter 0·001 inch gave the best effect.

3. Experiments were then tried with wires 6 inches in length and 0·001 inch diameter of different materials, viz., gold, iron, aluminium, silver, copper, palladium, and platinum, and they came out in the following order of merit:—

Platinum	Very clear.
Aluminium	Very variable.
Palladium	Clear.
Iron	Clear.
Copper	Faint.
Silver	Faint.
Gold	Very poor.

4. The effect of mechanical strain was tried. It was found not to vary the effect. When once the requisite tension, which varied with each metal, was obtained, further tightening up did not vary the clearness or loudness of articulation.

Gold would scarcely bear the tension required to reproduce sonorous vibrations, hence its low position.

5. Very thin carbon pencil, ·0625 inch diameter, was tried under compression and under tension, but no effect whatever was experienced unless a bad joint was made, when at once a faint microphonic effect was apparent.

6. No sibilant sounds whatever could be reproduced.

7. That the effect was due to heating and cooling was shown by the fact that it was possible to increase the current to such a strength as to render the temperature of the wire sensible to the touch, and then to make its elongation and contraction by low sounds evident to the eye.

It therefore appears from these experiments that wires conveying those currents of electricity which are required for telephonic purposes expand and contract as they are heated and cooled, and as the variations in the strength of the current are small compared with the strength of the current itself, the expansion and contraction vary in the same ratio as the condensation and rarefaction of the air particles conveying the sonorous vibrations which produced these vibrations.

The mechanical changes, or molecular vibrations in the wire, due directly or indirectly to telephonic currents, which result in the reproduction of sound, bear a close analogy to the mechanical changes due to the direct transmission of sound, but with this important difference, that while the vibrations due to sound are progressive along the wire, and their velocity is low and easily

measured, those due to thermal effects are practically instantaneous, and therefore affect simultaneously the whole length of the wire.

NOTE.—De la Rive, in 1843 (*vide* "Electricity," vol. i. p. 304), observed that an iron wire emitted sounds when rapid discontinuous currents were passed through it; but he attributed the effect to magnetism, for he failed to obtain the same effect in non-magnetic wires like platinum or silver.

Graham Bell found, in 1874, that a simple helix without an iron core emitted sounds, and (in 1876) that very distinct sounds proceed from straight pieces of iron, steel, retort carbon, and plumbago, when conveying currents.

Prof. Hughes showed that his microphone was reversible, that is, that it could receive as well as transmit sonorous vibrations.

Mr. Weisendanger (*Telegraphic Journal*, October 1, 1878) reproduced sounds on a microphonic receiver which he called a thermophone, and attributed the effect to its true cause, viz., the expansion of bodies under the influence of heat, which, in fact, is the explanation of all microphone receivers.

Ader reproduced speech by the vibrations of a wire conveying currents of electricity, but he found that only magnetic metals were effective, and therefore, like De la Rive, he attributed the result to magnetic agencies (*vide* Count du Moncel, *Telegraphic Journal*, March 1, 1879).

These and many other sonorous effects of currents on wires may be really due to such heat-effects as I have described.

Chemical Society, May 20.—Prof. H. E. Roscoe, president, in the chair.—The first paper was entitled, "On the Action of Air upon Peaty Water," by Miss Lucy Halcrow and Dr. Frankland. In consequence of the statements of Dr. Tidy in his paper on river-water, as to the rapid oxidation of peaty matter in running water, the authors have studied upon an experimental scale the action of exceptionally strong peaty water upon atmospheric air. The peaty water was exposed to air and light with and without agitation; the organic matter in the water and the oxygen in the inclosed air were determined before and after each experiment. It was found that minute quantities of oxygen were absorbed by the peaty water, but even when some water was shaken for ten and a half hours in a bottle fixed on the connecting-rod of a steam-engine making 100 strokes per minute, only 2½ per cent. of the organic matter was oxidised, assuming that all the oxygen taken up was employed in the oxidation of organic matter. The authors therefore conclude that if peaty matter is oxidised the process takes place with extreme slowness.—Dr. Frankland then read a paper on the spontaneous oxidation of organic matter. This was practically a criticism of the conclusions drawn by Prof. Tidy in his paper alluded to above. The author first referred to the belief so prevalent twelve years ago that water polluted with sewage quickly regains its original purity by spontaneous oxidation, and explained how this belief was upset by the quantitative evidence obtained by the Second Rivers Pollution Commissioners in 1868. He then criticised the results of Prof. Tidy, and pointed out some grave inconsistencies therein. Thus the Shannon, after flowing twenty-three miles through Loch Derg, has its organic elements diminished about 18 per cent., whilst the next flow of a mile effects a diminution of 38 per cent. A sample taken four miles lower down showed an increase of 75 per cent., &c. These inconsistencies could only be explained by want of care in taking and securing an average sample of the river at the different points. The artificial purification of mixtures of sewage and water effected by Prof. Tidy by running water through a series of shallow troughs was then considered, and the chief cause of the diminution of organic carbon and nitrogen attributed to the decomposition of the urea into ammonium carbonate. The author concludes that there is no evidence whatever of the destruction by oxidation of the dead organic matter of sewage by a flow of a dozen miles or so in a river, still less is there any ground for assuming that the organised or living matter of sewage is destroyed under like circumstances. The paper concludes with some statistics as to the effect of the water-supply on the spread of epidemics of cholera, &c. Prof. Huxley pointed out that all diseases which are caused by so-called germs are caused by bodies of the nature of bacteria, and that these organisms were plants, and were therefore extremely unlikely to be oxidised or destroyed by endosmose, as suggested by Prof. Tidy, and that it was quite conceivable that a water containing such bodies might be perfectly pure from a chemical point of view, and yet be as deadly as prussic acid. Prof. Tidy, in reply, pointed to the statistics of the last ten years, which proved that many towns which derived their water-supply from river-water which had been polluted with sewage were as free from fever, &c., as other towns supplied by deep-well water.

Physical Society, May 22.—The annual holiday meeting of this Society was held at Cambridge. On arrival there the party partook of luncheon in a hall of St. John's College, which had been kindly arranged for the purpose by the College authorities. Prof. W. G. Adams occupied the chair, and Mr. Warren De la Rue proposed a vote of thanks to the Master and Senior Fellows of the College for providing the hall. The vote was heartily accorded by the members, and after some remarks from Prof. Adams the party proceeded to the Cavendish Laboratory, where Lord Rayleigh, as vice-president of the Society, presided. The routine business of the meeting being waived, Lord Rayleigh described a plan for limiting the slit of a telescope so as to alter the angular interval with which it can deal. The interval is measured by means of a grating formed by winding a fine wire round two parallel screws of very fine thread.—Mr. Shaw exhibited a modification of Veinholdt's apparatus for distilling mercury, by which a kilogram of mercury can be distilled per hour.—Mr. Sydney Taylor exhibited a device for showing the motion of the particles of water in the transmission of a surface-wave. Sixteen disks were arranged in single file, each having a white spot on its face, and on turning a handle the disks rotated so that the spots, which represented particles of water, moved so as to present a wave-motion to the eye. Mr. Taylor also showed a manometric flame apparatus for exhibiting to the eye the difference of phase between two musical notes. This consisted in two bent tubes, into which the notes were sounded, and capable of being lengthened or shortened by hand like the pipes of a trombone. Opposite the ends of each of these tubes a sensitive flame was placed, and a rotating mirror showed the disturbance produced in the flames by the two different notes. A third flame exhibited the joint effect of the two notes. When the tubes were silent, the images of the flames on the revolving mirror were seen as plane bands; but when notes were sounded into the tubes they became serrated, and the serrations were like or unlike according as the phases of the notes were like or unlike.—Mr. Poynting exhibited a plan for altering the plane of polarisation of the two halves of a pencil of rays from the polariser, so that half the field may be made to appear dark when the other is bright, or both of equal brightness, at will.—Mr. Glazebrook described a method of measuring the rotation of the plane of polarisation of light by means of two spectra giving dark lines made to coincide.—Lord Rayleigh described a plan for demonstrating that yellow colour can be formed by combining red and blue together. He mixes a red solution of chromate of potash with a blue solution of litmus, and on pouring it into a glass cell of a certain thickness, the light transmitted through it is seen to be yellow. Plates of glass coated with gelatin impregnated with litmus and gelatin impregnated with chromate of potash and placed side by side also transmit yellow light. Lord Rayleigh finds, however, that the eyes of different persons vary considerably in their power of appreciating the tinge of the transmitted yellow, one deeming it greenish, another reddish, while a third considers it pure yellow. This peculiarity is not to be confounded with "colour-blindness," since all three persons would distinguish the red and green components accurately. Lord Rayleigh also exhibited a colour-box based on the Newtonian principle, first carried out by the late Prof. Clerk Maxwell, but of a small size.—Sir W. Thomson then proposed a vote of thanks to Lord Rayleigh, which was seconded by Prof. W. G. Adams, and the meeting then dispersed to examine the apparatus and appointments of the Cavendish Laboratory.

Meteorological Society, May 19.—Mr. G. J. Symons, F.R.S., president, in the chair.—Messrs. T. H. Edmonds, F. Ekless, A. H. Taylor, and T. Turner were elected Fellows of the Society.—The following papers were read:—Variations in the barometric weight of the lower atmospheric strata in India, by Prof. E. Douglas Archibald, M.A., F.M.S.—A sketch of the winds and weather experienced in the North Atlantic between lats. 30° and 50° during February and March, 1880, by Charles Harding, F.M.S. The period embraced in this paper includes the time during which H.M.S. *Atalanta* was on her homeward passage, as she left Bermuda on January 31. From the data collected it is shown that a gale blew in the Atlantic every day throughout the two months, excepting on February 21 and 24 to 27. With especial reference to H.M.S. *Atalanta* it appears probable that she would not have met with any exceptionally

severe weather earlier than about February 12 or 13, and allowing that she had averaged from five to six knots per hour on her homeward course, she would at that date have inevitably encountered a severe hurricane. A heavy gale is noted on the 12th in 38° N. and 45° W., which is in the direct homeward-bound track from Bermuda, and if the *Atalanta* had only averaged four knots per hour on her homeward course she would have fallen in with this gale. The storm of the 12th and 13th may fairly be considered as about the most severe during the two months here dealt with. It may be remarked that the Norwegian barque *Caspaei* was north of Bermuda on the 3rd, and was in the full force of the gale on the 12th; her distance made shows that the winds were favourable for a homeward passage from Bermuda. The correspondence from H.M.S. *Salamis*, published in the *Times* of May 6, states, on the authority of the captain of the *Caspaei*, "on February 12, in lat. 42° 43′ N., long. 39° 25′ W., while running before the wind, encountered the severest gale he had ever experienced. The ship would not steer, and could not be prevented from broaching to. She was thrown on her beam ends, and remained so for nineteen hours, the cargo of cotton keeping her afloat. Several ships were in sight at the time of the commencement of the gale, and were unable to lay to on account of its suddenness."—On the meteorology of Mozufferpore, Tirhoot, for the year 1879, by Charles N. Pearson, F.M.S.—Mr. D. Winstanley also exhibited his solar radiometer.

Mineralogical Society of Great Britain and Ireland, June 1.—General Meeting.—Prof. T. G. Bonney, F.R.S., vice-president, in the chair.—Messrs. G. Neist Walker, F.G.S., Alex. Murray, F.G.S., director of the Geological Survey of Newfoundland, Geo. S. Mackenzie, Ph.D., and Hjalmar Furuhjelm, Government Inspector of Mines, Helsingfors, were elected as Ordinary Members, and Mr. Robert M. Heddle was elected as an Associate.—The following papers were read and discussed:—On a new face on crystals of stilbite from Scotland and Western Australia, by Prof. M. F. Heddle, F.R.S.E.—On a portable chemical apparatus for quantitative work, by A. E. Arnold.—On kaolinite and kaolin, by J. H. Collins.—On new Scottish minerals, by Prof. Heddle.—Further notes on mineral growth, by T. A. Readwin.—Interesting specimens of minerals were exhibited by Messrs. F. W. Rudler, T. A. Readwin, J. R. Gregory, and Wm. Summers.—The next meeting of the Society will be held at Swansea in August, during the "British Association" week.

Paris

Academy of Sciences, May 31.—M. Edm. Becquerel in the chair.—The following papers were read:—On an automatic electric lamp, by M. Jamin. A development of the "burner" described before. Three pairs of carbons are set pendant within an oblong covered coil; one pair, having its points nearer than the others, gives rise to the arc first, and burns upwards, and when it is consumed the fusion of a brass wire causes the second pair to come into action (similarly with the third). The expenditure in horse-power and the total light increase up to nine lamps, then both diminish. (Numerical results are fully given.) The brightness of the points directed down is five times that the other way.—On the heat of combustion of the principal hydrocarbonised gases, by M. Berthelot. *Inter alia*, the heat in question is never equal to that of the component elements, and M. Berthelot indicates the nature of the differences.—On the cosmogonic ideas of Kant, *apropos* of a reclamation of priority by M. Schlötel, by M. Faye. He finds no similarity between M. Schlötel's citations from Kant and his own special ideas.—M. Bresse was elected Member in Mechanics in place of the late General Morin.—Synthesis of citric acid, by MM. Grimaux and Adam.—Researches on the albuminoid matters of crystallin as regard the non-identity of those that are soluble with the albumen of white of egg and of serum, by M. Béchamp. In the soluble part he finds two quite distinct albuminous matters (*phacozymase* and *crystalbumin*), and distinctly separates the insoluble matters of the crystallinian fibres from fibrine. He laid special stress on direct analysis and determination of rotatory power, regarding coagulation as of secondary importance.—On the use of volcanic sands in treatment of vines attacked by phylloxera, by M. Novi.—A list of memoirs sent in prize-competition was given.—The Secretary described M. de Candolle's work on "Phytography, or the Art of Describing Plants."—On the refractions of Bessel, by M. Radau.—On an extension to functions of two variables of Riemann's problem relating to hypergeometric functions, by M. Picard.—On a class of two functions doubly periodic, by M. Farkas.—Determination of three axes of a solid body on which centrifugal forces exert, through rotation, a maximum effect, by M. Brassinne.—On the equilibrium of elasticity of a rectangular prism, by M. Mathieu.—Telephone with magnetic superexcitation, by M. Ader. This is based on the principle that if a thin layer of iron or steel be placed before the poles of a magnet it is much more powerfully affected if an iron armature be placed behind than if the latter be not present.—Study of the distribution of light in the spectrum, by MM. Macé and Nicati. Two quantities of light are considered equal when, illuminating a given colourless object placed always at the same distance from the same observer, they enable him to perceive the details with the same distinctness.—On astigmatism, by M. Leroy. Heat liberated in the combustion of some isomeric alcohols of the fatty series, and of œnanthol, by M. Longuinine. Isomerism of substances having the same chemical function, but differing in internal structure, does not appreciably affect their heat of combustion and formation.—On freezing mixtures formed of two crystallised salts, by M. Ditte.—Crystallised hydrofluosilicic hydrate, by M. Kiessler.—Proportion of carbonic acid in the air; reply to M Riset, by M. Marié-Davy.—Preparation of malonic acid, by M. Bourgoin. He has simplified and improved the process.—Preparation of neutral sulphuric ether, by M. Villiers.—Presence in *Soja hispida* (Münch.) of a notable quantity of a substance soluble in alcohol, and easily transformable into glucose, by M. Levallois.—Functions of the swimming bladder of fishes, by M. Marangoni. It rules the migration of fishes. They have to counteract its action with their fins. It produces a double instability, one of level, the other of position.—Researches on the structure of the axis below seminal leaves in cotyledons, by M. Gérard.—Journey from Biskra among the Touaregs, by M. Roche. This gives some geological details.—On the structure and development of the dentinary tissue in the animal series, by M. Magitot.—On the mucus of the cloacal region of the rectum, by MM. Herrmann and Desfosses.—On the inoculability of symptomatic *charbon*, and the characters which differentiate it from splenic blood, by MM. Arloing, Cornevin, and Thomas. The microbe by which the disease is transmitted is quite distinct from the *Bacillus anthracis*.—On M. Rohlfs' journey of exploration into the Eastern Sahara, by M. Berlioux.—French explorations in Central Africa, by M. Fontane. One of the two proposed scientific and hospital stations (the eastern one) is to be established at Kirassa, near Kiora, about 250 km. from Bagamoyo; and Capt. Bloyet, who is to superintend it, has left Marseilles with that object. M. Savorgnan de Brazza has been charged to explore the region about the sources of the Ogooué, and fix a point for the western station; Dr. Ballay accompanies him.—M. Jimenes presented a celestial map projected on the horizon of Mexico.

TWO DARWINIAN ESSAYS

Studies in the Theory of Descent. By Dr. Aug. Weismann, Professor in the University of Freiburg. Translated and Edited by Raphael Meldola, F.C.S., Secretary of the Entomological Society of London. Part I. On the Seasonal Dimorphism of Butterflies, with Two Coloured Plates. (London: Sampson Low, Marston, and Co., 1880.)

Degeneration. A Chapter in Darwinism. By Prof. E. Ray Lankester, F.R.S. NATURE Series. (Macmillan and Co., 1880.)

THE first of Dr. Weismann's "Studies," of which Mr. Meldola has given us an excellent translation, with the author's latest notes and additions, is devoted to a thorough examination of the well-known but hitherto little understood phenomenon of the seasonal forms of butterflies. For the benefit of those unacquainted with entomology we may state, that many butterflies have two, or even three broods in a year. One brood appears in spring, their larvæ having fed during the preceding autumn and passed the winter in the pupa state, while the others appear later in the year, having passed rapidly through all their transformations and thus never having been exposed to the cold of winter. In most cases the insects produced under these opposite conditions present little or no perceptible difference; but in others there is a constant variation, and sometimes this is so great that the two forms have been described as distinct species. The most remarkable case among European butterflies is that of *Araschnia prorsa*, the winter or spring form of which was formerly considered to be a distinct species and named *Araschnia levana*. The two insects differ considerably in both sexes, in markings, in colour, and even in the form of the wings, so that till they were bred and found to be alternate broods of the same species (about the year 1830) no one doubted their being altogether distinct.

In order to learn something of the origin and nature of this curious phenomenon Dr. Weismann has for many years carried on a variety of experiments, breeding the species in large numbers and subjecting the pupæ to artificial heat or cold for the purpose of hastening or retarding the transformation. The result of these experiments is, that by subjecting the summer brood to severe artificial cold in the pupa state, it may be made to produce perfect insects the great majority of which are of the winter form; but, on the other hand, no change of conditions that have yet been tried have any effect in changing the winter to the summer form. Taking this result in connection with the fact that in high latitudes where there is only one brood a year it is always the winter form, Dr. Weismann was led to the hypothesis that this winter form was the original type of the species, and that the summer form has been produced gradually, since the glacial epoch, by the summer becoming longer and thus admitting of the production of a second or summer brood. This explains why the production of the winter form (*A. levana*) from summer larvæ is easy, it being a reversion to the ancestral type; while the production of the summer form (*A. prorsa*) from autumnal larvæ is impossible, because that form is the result of gradual development; and processes of development which have taken thousands of years to bring about cannot be artificially reproduced in a single season.

This hypothesis was supported by experiments with another two-brooded species, *Pieris napi*, with similar results, the winter form being produced with certainty by the application of cold to summer pupæ; and Mr. Edwards, in America, has made similar experiments with the various forms of *Papilii ajax*, finding that the summer broods can be changed into the winter form by the application of cold, while the winter broods can never be made to assume the summer form by hastening the process of transformation. In the Arctic regions and in the high Alps there is only one form of *Pieris napi*, which very closely resembles the winter form of the rest of Europe, and this could never be the least changed by rapidly developing the pupæ under the influence of heat.

Another curious case is that of one of the Lycænidæ (*Plebeius agestis*) which exhibits three forms, which may be designated as A, B, and C. The first two, A and B, are alternate broods (winter and summer) in Germany, while in Italy the corresponding forms are B and C, so that B is the summer form in Germany and the winter form in Italy. Here we see climatic varieties in process of formation in a very curious way.

That temperature during the pupa stage is a very powerful agent in modifying the characters of butterflies, is well shown by the case of *Polyommatus phlœas*. The two broods of this insect are alike in Germany, while in Italy the summer brood has the wings dusky instead of copper-coloured. The period of development is exactly the same in both countries, so that the change must, it is argued, be attributed to the higher temperature of the Italian summer. It has been noticed that in Italy a large number of species of butterflies are thus seasonally dimorphic which are not so in Central and Northern Europe.

Dr. Weismann lays great stress on the varied effects of temperature in modifying allied species or the two sexes of the same species, from which he argues that the essential cause of all these changes is to be found in peculiarities of physical constitution, which cause different species, varieties, or sexes to respond differently to the same change of temperature; and he thinks that many sexual differences can be traced to this cause alone without calling in the aid of sexual selection. The general result arrived at by the laborious investigation of these phenomena is, that—"a species is only caused to change through the influence of changing external conditions of life, this change being in a fixed direction which entirely depends on the physical nature of the varying organism, and is different in different species, or even in the two sexes of the same species;" and he adds:—"According to my view, transmutation by purely internal causes is not to be entertained. If we could absolutely suspend the changes of the external conditions of life, existing species would remain stationary. The action of external inciting causes, in the widest sense of the word, is alone able to produce modifications; and even the never-failing 'individual variations,' together with the inherited dissimilarity

of constitution, appear to me to depend upon unlike external influences, the inherited constitution itself being dissimilar because the individuals have been at all times exposed to somewhat varying external influences." The present writer has arrived at almost exactly similar conclusions to these, from a study of the geographical distribution and specific variation of animal forms, as stated in an article on "The Origin of Species and Genera," which appeared in the *Nineteenth Century* of January last, and it is gratifying to find them supported by the results of a very different line of inquiry, and by the authority of so eminent and original an observer as Dr. Weismann.

The second work referred to in our heading, is Prof. Lankester's British Association evening lecture last year at Sheffield, now republished with illustrations as one of the useful little volumes of the "Nature Series." It discusses the little-known phenomena of "Degeneration" as a phase of development much more general, and of far greater importance than is usually supposed. Degeneration causes an organism to become more simple in structure, in adaptation to less varied and less complex conditions of life. "Any new set of conditions occurring to an animal which render its food and safety very easily attained, seem to lead as a rule to degeneration; just as an active healthy man sometimes degenerates when he becomes suddenly possessed of a fortune; or as Rome degenerated when possessed of the riches of the ancient world. The habit of parasitism clearly acts upon animal organisation in this way. Let the parasitic life once be secured, and away go legs, jaws, eyes, and ears; the active and highly-gifted crab, insect, or annelid may become a mere sac, absorbing nourishment and laying eggs."

We see incipient cases of degeneration in the loss of limbs of the serpentiform lizards and the pisciform mammals; the loss of eyes in the inhabitants of caverns and in some earth-burrowers; the loss of wings in the Apteryx and of toes in the horse; and, still more curious, the loss of the power of feeding themselves in some slave-holding ants. More pronounced cases are those of the barnacles—degenerated crustacea, and the mites—degenerate spiders; while we reach the climax of the process in Ascidians—degenerate vertebrates, and such mere living sacs as the parasitic Sacculina and Lernæocera, which are degenerated crustaceans. Not only such lesser groups as the above, but whole orders may be the result of degeneration. Such are the headless bivalve mollusca known as Lamellibranchs, which are believed to have degenerated from the head-bearing active cuttle-fish type; while the Polyzoa or Moss-polyps stand in the same relation to the higher Mollusca as do the Ascidians to the higher Vertebrates.

While discarding the hypothesis that all savages are the descendants of more civilised races, Prof. Lankester yet admits the application of his principle to explain the condition of some of the most barbarous races—"such as the Fuegians, the Bushmen, and even the Australians. They exhibit evidence of being descended from ancestors more cultivated than themselves." He even applies it to the higher races in intellectual matters, and asks: "Does the reason of the average man of civilised Europe stand out clearly as an evidence of progress when compared with that of the men of bygone ages? Are all the inventions and figments of human superstition and folly, the self-inflicted torturing of mind, the reiterated substitution of wrong for right, and of falsehood for truth, which disfigure our modern civilisation—are these evidence of progress? In such respects we have at least reason to fear that we may be degenerate. It is possible for us—just as the Ascidian throws away its tail and its eye and sinks into a quiescent state of inferiority—to reject the good gift of reason with which every child is born, and to degenerate into a contented life of material enjoyment accompanied by ignorance and superstition."

This is very suggestive; but we may, I think, draw a yet higher and deeper teaching from the phenomena of degeneration. We seem to learn from it the absolute necessity of labour and effort, of struggle and difficulty, of discomfort and pain, as the condition of all progress, whether physical or mental, and that the lower the organism the more need there is of these ever-present stimuli, not only to effect progress, but to avoid retrogression. And if so, does not this afford us the nearest attainable solution of the great problem of the origin of evil? What we call evil is the *essential* condition of progress in the lower stages of the development of conscious organisms, and will only cease when the mind has become so thoroughly healthy, so well balanced, and so highly organised, that the happiness derived from mental activity, moral harmony, and the social affections, will itself be a sufficient stimulus to higher progress and to the attainment of a more perfect life.

For numerous instructive details connected with degenerated animals we refer our readers to the work itself—truly a small book on a great subject, and one which discusses matters of the deepest interest, alike to the naturalist and the philosopher.

ALFRED R. WALLACE

NATURE'S HYGIENE

Nature's Hygiene: a Series of Essays on Popular Scientific Subjects, with Special Reference to the Chemistry and Hygiene of the Eucalyptus and the Pine. By C. T. Kingzett. (London: Baillière, Tindall, and Cox, 1880.)

THE subject of this book is, practically, Peroxide of Hydrogen. Such a title as "Peroxide of Hydrogen, with Special Reference to its Sanitary Applications," might not have proved so taking as "Nature's Hygiene," but it would have been quite as descriptive of the subject-matter of the work. Mr. Kingzett strives to show that the position which has been assigned to ozone as "Nature's purifier and disinfectant," is not altogether merited by that body, but that it should rather be given to peroxide of hydrogen. There can be no doubt that these substances have been frequently confounded, and that in numerous instances reactions which have been attributed to ozone have been caused by hydrogen peroxide. It has been stated, for example, that the aromatic parts of flowers produce ozone, and that this substance is formed in considerable quantity by plants rich in essential oils—indeed the late Dr. Daubeny was of opinion that the oxygen evolved from plants by the decomposition of carbon dioxide in sunshine was always more or less ozonised; and other observers have sought to show that

oil of turpentine and substances allied to the terpenes have the property of transforming oxygen into ozone. There is no doubt whatever that ozone is soluble in oil of turpentine; this is incontestably proved by the experiments of Soret, who, as all chemists know, has made capital use of the fact, but this is quite another thing to saying that oil of turpentine *generates* ozone. This confusion between ozone and hydrogen peroxide has mainly arisen from the difficulty of discriminating between the two substances, and it is only since the researches of Struve, made about ten or eleven years since, that the presence of the latter body in the air may be said to have been demonstrated. Observers were led astray by the supposition that the simultaneous existence of the two substances was impossible; chemically speaking, they were held to be incompatible. Recent observations have shown that the opinions hitherto held on this point must be modified. We are at present very much in the dark as to the causes which lead to the formation of peroxide of hydrogen in nature, but that many plants, and especially those which secrete essential oils, contribute to its production is almost certain. In the book before us Mr. Kingzett has collected a mass of evidence on this matter, and has presented it in an eminently readable and interesting form. Perhaps the most valuable part of the work is that which relates to the power exercised by the various members of the genus Eucalyptus in preventing or destroying malaria—which power according to our author is related to their property of forming peroxide of hydrogen.

The *Eucalyptus globulus* was discovered by Labillardière in Tasmania towards the close of the last century, but it is only within the last quarter of a century that its anti-miasmatic properties have become known to Europeans. To whom the credit of the discovery is due is not clearly made out. M. Ramel, Baron Müller, and Sir W. Macarthen appear to have been among the first to draw attention to its extraordinary power, and seeds of the tree were sent by them from time to time to Europe. The testimony in support of this power is most convincing. In marshy districts near Eucalyptus forests fever seems to be unknown, and in parts of Corsica and Algeria where the tree has been planted for the sake of its reputed virtues endemic fevers have been stamped out. M. Gimbert, in a report to the French Academy, instanced the case of a farm situated in a pestilential district about twenty miles from Algiers, where by planting a number of the trees the character of the atmosphere was entirely changed. Similar testimony comes from Holland, the South of France, Italy, California, and many other parts of the world as to the febrifugal attributes of this tree. In no case is the evidence more convincing than in that of Algeria, as we have it related to us by Dr. Santra, and, quite recently, by Consul Playfair. Large tracts of land have been quite transformed by the agency of the "fever-destroying tree" as it has come to be called, and wherever it is cultivated fevers are found to decrease in frequency and intensity. Fewer districts in Europe have a more evil reputation than the Campagna as a veritable hot-bed of pestilential fever, and people who know the country round Rome may remember the monastery at Tre Fontane on the spot, as tradition tells, that St. Paul met his death. Life in this monastery meant death to the monks, but since the Eucalyptus has been planted in the cloisters fever has disappeared and the place has become habitable.

That the aromas of plants have in all ages been held to act as preventives of disease, especially against those of an infectious or malarial type, is well known, and in every visitation of plague which has afflicted this country we read of people carrying strong-smelling gums or balsams about their persons. The physicians of a bygone time had vinaigrettes in the handles of their canes to protect them from the exhalations of their patients, and the miserable wretches who came out of the fever-haunted prisons and bridewells of a century or two ago to stand their trials were surrounded by some aromatic herb to protect the court from possible contagion. Even the chaplain as he accompanied the doomed man to the gibbet had presented to him a bouquet as a precaution against the dreaded jail-fever.

Whether peroxide of hydrogen is invariably produced by the process of oxidation of the aromatic parts of plants is not yet proved, but that it frequently is so seems beyond question. There can be no doubt too that this substance is a very powerful antiseptic; the experiments of Mr. Kingzett and others are quite conclusive on this point.

OUR BOOK SHELF

The Science of Voice Production and Voice Preservation, for the Use of Speakers and Singers. By Gordon Holmes, Physician to the Municipal Throat and Ear Infirmary. (London: Chatto and Windus.)

THE author says that this work is an abridgment of his "Vocal Physiology and Hygiene," of which a notice has already appeared in NATURE (vol. xxi. p. 271), and that it is intended "to furnish persons who make an artistic or professional use of the vocal organs with a concise account of those relations of the voice to physical and medical science which are only cursorily alluded to, or passed over altogether, in treatises on elocution and singing."

The account is concise enough, in the sense of not occupying much space, if we omit the chapter headed "Hygiene of the Voice," which is mainly occupied with general hygiene; but we greatly doubt whether those who "make an artistic or professional use of the vocal organs" will derive much advantage from its study, that is, whether they will be able to carry away much that will be of use to them. In striving to be concise the author seems to have become vague. Although, of course, he must be professionally well acquainted with the details of the vocal organs and their laryngoscopic appearance, he has not succeeded in conveying a clear knowledge of so much as it imports the singer and public speaker to know. Nor are his woodcuts of the larynx at all satisfactory; those, for example, of "the larynx when sounding a note about the level of the ordinary speaking voice," and "during the emission of falsetto notes," being calculated to convey false impressions to those who see them for the first time. His knowledge of the physics of sound, and especially of phonetics, appears to be entirely secondhand. There is the same impression conveyed by his treatment of the registers and voice training for singers. The consequence is a want of definiteness and exactness in all these important branches of his subject. Thus, on p. 2, he tells us that sound travels through air at the rate of about 1,090 feet in a second, but neglects to add "at freezing temperature," or that it goes faster when the air is heated, so that, in fact, about 1,120 feet at 60° F. is the more common rate. At

other times his language is rather singular, as when he says that stammering "frequently arises from a muscular defect, giving rise to a *clumsiness in getting the tongue round one or more letters*" (p. 94), or speaks of the vocal bands being "tensed" (p. 105), or says that "musical gifts of voice are rather *phylogenetic* in their origin," the word in italics not appearing even in Mayne, or speaks of "living up hills" (p. 146). In a book written for singers and public speakers Latin and Greek and technical expressions should certainly be explained, if not avoided, such as *phylogenetic*, already adduced, and *frænum linguæ* (p. 95). The article on hygiene conveys a good deal of information, but we suspect most readers will rather remember the amusing account of the dietetic habits of singers, quoted from other sources, on p. 114, than be able to dig out what relates to the voice from the great mass of other matter. In conclusion, we cannot help feeling that the words "the science of," in the title, are not justified by the book itself, and might be advantageously replaced by the single word "on."

Ceylon Coffee Soils and Manures: a Report to the Ceylon Coffee Planters' Association. By John Hughes. (London: Straker Bros. and Co., 1879.)

THE writer of this report has at least gathered together a large amount of useful information about the coffee plant, coffee soils, and coffee manures. As an agricultural chemist he has, not unnaturally, attributed excessive importance to the composition and condition of the soils in which healthy and diseased coffee trees are found; manures also are indicated as amongst the chief remedial measures. Doubtless, the proper maintenance of the "condition," as it is technically termed, of coffee soils has been woefully neglected. Indeed, where there is neither rotation nor even alternation of crops the difficulty of securing continued vigour of growth and ample crops of fruit must be considerable, even when soils are rich and seasons favourable. But let any adverse influences, whether of excessive rainfall, or of mechanical and chemical injury to the soil occur, and then the plant is more likely to succumb to the attacks of its enemies, vegetable and animal. Thus wheat straw deprived of adequate supplies of soluble silica becomes more subject to injury from insects and mildew. Other examples might be found of a connection between certain deficiencies in the soil and certain diseases in the plant, but it is unsafe to make a hasty generalisation on this point. In combating the coffee-leaf disease we must first of all devote ourselves to the fungus which is its direct cause. There can be little doubt that calcium sulphide, which proved so efficient a means of destroying the *Oidium* of the vine will be equally destructive to the *Hemileia vastatrix*. A mixture of sulphur and quicklime, or a wash made by simply boiling these two materials together, is much less active.

When Mr. Hughes makes suggestions about the sources of manurial substances available for Ceylon, about the making and preservation of cattle and vegetable manure, and about terracing and draining, we can heartily endorse his recommendations. And when he gives us a number of careful analyses, some of which are of considerable interest, even apart from their connection with the growth of coffee, we are grateful for information which is sure to become useful under some circumstances and at some time. But there are certain portions of Mr. Hughes's Report which seem to have been introduced with no special object, or which are of questionable value. We hardly need to be taught that "Planters want a practical remedy rather than an elaborate description of the disease" (p. 140). The appearance of what look like recommendations of the manurial preparations of particular manufacturers should have been avoided (pp. 27 to 30). We could have spared the repetition of the well-worn table of manurial values on p. 100, and the analysis of Bude sand (p. 36). The term *granitic* as applied (p. 37) to a limestone containing over 70 per cent. of calcium and magnesium carbonates needs a word of explanation. Of really interesting data furnished by Mr. Hughes we may cite the analyses of castor-seed cakes (p. 15), in which the nitrogen is shown to differ widely—brown and black cakes containing but 4½ per cent., while white cakes show no less than 7½. Although we do not believe in the third decimal places (how often can we chemists secure accuracy in the tenths?) in Mr. Hughes's soil analyses (pp. 46, 53, 65, 72, 77, 81, 150)—particularly as his phosphoric acid determinations were not made by the molybdic acid process—yet these results represent a mass of laborious researches, and ought to furnish much material for the management of Ceylon coffee soils. The analyses of healthy and diseased coffee-leaves (pp. 142-144) deserve careful study; they point unmistakably to the fungoid origin of the disease. A. H. C.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Cloud Classification

BETWEEN M. Poëy and his latest critic (NATURE, vol. xxii. p. 96) it would be impertinent for me to interfere. But until my objection to a part of Howard's original classification has met with some response from those who maintain the adequacy of that classification I must continue, at the risk of some repetition, to call attention to this objection. It can be stated briefly, and I do not see why the answer thereto, if such exist, should be deferred as too long for discussion.

E. H. appears to admit that an observer, when within a cloud (which is then to him a fog), cannot distinguish *cumulus* from *stratus*. He, however, elevates the stratus, or rather one variety of it, "a few feet (or even inches) from the earth," so as to cut "the taller trees in a horizontal line, leaving their tops and bottoms free." He proposes to shelve the question "whether it is desirable to use the term 'stratus' for clouds in a totally different sky region, which differ both in their origin and their nature from the true stratus" (*i.e.*, from the *stratus* of the sky-region of half-length elms in the Thames basin). Now it is precisely this question which the large and growing class of observers, who wish to record the modifications of clouds, can no longer permit to be left unsettled. If clouds are to be classified according to their form at all, some name is absolutely required for a class of clouds which is in all latitudes common, and in the higher predominant. These are the clouds to which the observers can neither give the title *cumulus* nor the title *cirrus*, the clouds which are disposed in beds or layers whose vertical thickness is small. When in trifling amount they arrange themselves in irregular disks or patches capable of being occasionally mistaken for *cumulus* when in the zenith, but elsewhere seen as streaks or threads transverse to the meridian. When in large amount they cover a great portion or the whole of the sky with a shallow and nearly level canopy. In England, putting together observations made at all hours of day and night, clouds belonging to this class are recorded in about 60 per cent. of the observations. Of observations made at 2 p.m. they occur in about 38 per cent.; of observations made between sunset and sunrise in upwards of 90 per cent. Of observations made at all hours in the English Midlands from October, 1879, to February, 1880, inclusive, they were recorded in 83 per cent. To leave this class nameless is intolerable. To give to them either of the compound titles *cumulo-stratus* and *strato-cumulus* is objectionable, because in form they do not resemble *cumulus* at all (I might add that to a defender of Howard's unamended system they also do not resemble *stratus* at all, differing, as we are told, not only in elevation, but in "origin and nature," both from ground-fog and middle-tree fog). A similar objection lies against the application to these clouds of

the terms *cirro-stratus* and *strato-cirrus*. Finally the terms *cumulo-stratus* and *cirro-stratus* are sorely needed for varieties of clouds intermediate between the class I have described and the *cumulus* and *cirrus* types, if any part of Howard's terminology is to be left to us at all.

It would be a pity that that terminology, lucid and expressive, should perish, merely because, to a few minds, the originator of a system must needs appear infallible, and his classification perfect as Minerva when issuing from the head of Jupiter. I think that Luke Howard would have been the last to put forward such a claim. W. CLEMENT LEY

The Motion of Fluids

PROF. REYNOLDS, in the course of his review (NATURE, vol. xxi. p. 342) of my book on the above subject, cites two instances in which I have been guilty of what he considers loose and vague reasoning. I would ask space for a few remarks on the points in question.

To take the more important matter first, Prof. Reynolds says, *apropos* of a certain proof of the velocity-potential theorem given in Art. 23:—

"Mr. Lamb has offered a proof of this now historic theorem, which, if judged by the space it occupies, should be much simpler than the acknowledged proofs of Cauchy and Stokes. As no authority is cited, it would appear that this proof is here given for the first time. If so, the author has done himself great injustice in not examining or explaining his reasoning more closely. For, as it stands, it suggests the idea that he has ignored the fact that dx, dy, dz, on the left of his equation, are integrals through a finite time, and hence, inasmuch as he has given no reason to the contrary, may be of a different order of magnitude from their initial values, da, db, dc, which appear on the right of his equation. If this is not so it is a peculiarity of the motion of continuous fluid, and needs establishing; otherwise we might infer that two people who had once shaken hands could never after be so much as a mile apart."

Prof. Reynolds, who himself strongly recommends the careful study of "work from the master's hand," will hardly take it amiss if I ask him to turn to the proofs which he justly cites as classical, and to notice that they contain, one of them (Cauchy's) in exactly the same form, the other in a form which is mathematically equivalent, the very assumption which he here calls in question. The assumption is in fact nothing more than a tacit limitation, which is made at the very outset of the subject, as to the class of motions which are proposed for study. In the "Eulerian" method it is implied that the first derivatives of the component velocities u, v, w with respect to the co-ordinates x, y, z are to be everywhere and always finite throughout the motion considered; in the "Lagrangian" method the corresponding, and equivalent, assumption is that the derivatives $\frac{dx}{da}$, $\frac{dx}{db}$, $\frac{dx}{dc}$, &c., and also $\frac{d^2x}{da\,dt}$, $\frac{d^2x}{db\,dt}$, $\frac{d^2x}{dc\,dt}$, &c., are to be finite. We do not assert that these are universal characteristics of fluid motion, for it is easy to imagine cases in which they are violated; we merely exclude such cases *ab initio* from the scope of our investigations. But, in one form or another, these fundamental limitations are, from the point of view of analytical hydrodynamics, unavoidable; they are made implicitly every time we write down the equations of motion, and it is therefore not surprising that they should be found to be essentially involved, not only in the proof which Prof. Reynolds on this account criticises, but in every other proof of the velocity-potential theorem which has yet been propounded.

I have only to add that the proof in question is, and professes to be, merely a very obvious corollary to H. Weber's transformation of the Lagrangian equations.

The other passage of Prof. Reynolds's review which I wish to notice is as follows:—

"There is a considerable amount of vagueness attending the author's use of the term *particle*. Having rightly defined fluids as being such 'that the properties of the smallest portions into which we can conceive them divided are the same as those of the substance in bulk,' he proceeds to reason about a particle as though it were a discrete quantity, the position of which is defined by some point, thus ignoring the fact that, according to his definition, the same particle of fluid may at one time be a sphere, at another a filament of indefinite length, or a sheet of indefinite breadth. This vagueness appears to have led him into error in Art. 11."

A good deal of this criticism is, I think, met by the remarks already made. In a fluid moving subject to the conditions I have stated, only finite changes of shape can be produced in a moving element within a finite time.

Prof. Reynolds does not indicate the precise nature of the "error" which he finds in Art. 11. After a careful reconsideration, the argument of that article appears to me to be sound; but I am free to confess that it is not stated with all the clearness desirable, and that the article is further disfigured by an unfortunate clerical error in the foot-note, where "$u = \pm\sqrt{x}$" should be read for "$u = \pm x$." HORACE LAMB

Adelaide, March 30

On the Physical Aspects of the Vortex-Atom Theory

WILL any charitable person explain a difficulty which I (and other non-mathematical people) have encountered when seeking to understand and be satisfied with this theory?

The only proof of those properties of vortex rings which match the physical properties of atoms that I have met with is that in Besant's "Hydromechanics"; and is based on the initial-co-ordinate method.

Now it seems to me that this method assumes what is equivalent to the permanence of the vortex filament; so that in proving the latter by use of this system of co-ordinates we may be merely arguing in a circle.

For it assumes that if initially we have any infinitesimal tetrahedron $\delta a \,.\, \delta\beta \,.\, \delta\gamma$, then after the *finite time*, t, this will still form a tetrahedron $\delta x \,.\, \delta y \,.\, \delta z$.

Now I cannot see that one can assume this; that—to use the words in a late article of NATURE—"if two people have once shaken hands they can never be 100 miles apart."

And this inseparability of the particles of a fluid thus *assumed* bears a very close relation to the permanence of the vortex filament which we wish to prove. W. L.

Cheltenham, May 29

[It appears to us that our correspondent here confuses between the permanence of any fluid filament and the permanence of the vortex character of the filament. The assumption that every filament remains continuous cannot be said to be equivalent to assuming that the direction of the filament at every point remains coincident with the axis of rotation of its constituent elements at that point, which is what Helmholtz has taught us.—ED.]

The Aurora Borealis and its Colours

WITH regard to Drs. De La Rue and Müller's paper on the Aurora (NATURE, vol. xxii. p. 33) there is still a point I should like to see explained. Is it considered by physicists that in electric discharges similarity of colour is sufficient to indicate similarity of constitution, even when their spectra are quite unlike? The paper, together with the reply to Prof. Smyth, certainly seems to imply this; though I have not previously seen it stated to be the case.

With regard to the red part of auroræ, so far as my observations indicate its position, they show it to be above the greenish part in the auroræ seen here; though according to Weyprecht's observations, it is below the green in the Arctic regions.

Sunderland, June 9 T. W. BACKHOUSE

A New Audiphone

FURTHER experiments on the timbre of musical instruments as rendered by the audiphone have led me to the selection of the following as a distinct improvement on the birchwood veneer, both for musical purposes and also for ordinary conversation. It has the same advantage as my previous form in not requiring to be held by the hand, it costs nothing, and requires no making. Take a sheet of stiff brown paper about 11 × 15 inches, the paper being such as is ordinarily used for making up heavy parcels. Put the ends together, the middle forming a loop, and hold the ends between the teeth. The paper must be pretty stiff, as the loop must stand out round and full, and of course the paper must be without folds or creases. THOS. FLETCHER

Museum Street, Warrington

Crystal-Ice

IN reference to the "crystal ice" proposed by Dr. Calantarients, of Scarborough, for skating upon with ordinary skates,

it may not be generally known that more than thirty years ago a skating pond was constructed in Liverpool, consisting, I believe, entirely of crystallised Glauber's salt. I have a perfect recollection of this miniature lake with its grotto-like surroundings, of its black-looking ice with innumerable white scorings marking the tracks of the skaters, yet, strange to say, I cannot remember whether I skated on it myself. The impression that I did seems to be confused with other skating scenes. This perhaps does not look like very reliable evidence, but that the "rink" (under another name) of artificial ice did exist, and was popular, will no doubt be affirmed by many witnesses besides myself. The date would be about 1845, if I am not mistaken, and the speculation ultimately failed owing to a public impression (possibly a wrong one) that the exhalations from the surface of the pond caused sickness and headache. R. H.

The Stone in the Swallow

YOUR correspondent, Dr. P. P. C. Hoek, requests information respecting the origin of the fable to which the poet Longfellow refers at the end of the first part of "Evangeline"—"The stone in the nest of the swallow." In Burton's "Anatomy of Melancholy," p. 434, at the top (Wm. Tegg's edition), after describing in the delightfully quaint style of the age the curative virtues of various stones, he quotes the following:—

"In the belly of a swallow there is a stone called 'chelidonius,' which, if it be lapped in a fair cloth and tied to the right arm, will cure lunatics, madmen, make them amiable and merry."

In a foot-note there are references made to the following authors:—Albertus, Eucellius, cap. 44, lib. 3; Plin, lib. 37, cap. 10; Jacobus de Dondis, &c.

It seems probable that Longfellow got his version of the story from some of the descendants of the French Acadians, to whom the poem relates, and it may have come down from the same sources from which Burton derives his account of the matter. It may be noted that the two versions do not in any way clash, Burton's simply referring to the whereabouts of the stone, "in the belly of the swallow," its name and benefits to those afflicted with insanity; while Longfellow's version relates more to the finding and locality of the stone and its uses to the young swallows, leaving its supposed value to man, depending on the general term of being "lucky." JOHN LOCKE

Trinidad, West Indies, May 24

Stags' Horns

IN reference to the opinions recently expressed in your journal regarding the disappearance of the horns of stags, deer, &c., I may mention that this is usually attributed here to the action of rodents rather than of the deer themselves. Even if a deer should occasionally be seen gnawing a horn it would be very difficult to account for the disappearance of all the annual crop of antlers in this way. From the nature of their dentition (having no incisor teeth in the upper jaw) the destruction of such a mass of hard material must be very difficult. Moreover slight examination will show whether the tooth marks are those of the large teeth of a deer or of the small incisors of a rodent.

Antioch College, Ohio, U.S.A. E. W. CLAYPOLE

ON SOME POINTS CONNECTED WITH TERRESTRIAL MAGNETISM

I HAVE on more than one previous occasion brought forward some of the various points which are here grouped together. These points are three in number.

(α) Regarding the sustaining power of the earth's magnetism.

(β) Regarding the diurnal and other changes of the same.

(γ) Regarding earth currents and auroras.

I may state at once that this only professes to be a working hypothesis.

(α) *Regarding the Sustaining Power of the Earth's Magnetism.*—I do not here intend to discuss the cause of the earth's magnetism, but I would ask in the first place if it is not possible that this cause may be something small and one which (assuming it to continue at the present moment) we may not readily perceive. If we assume this cause or magnetic nucleus to be small is it not possible to imagine that there is a machinery which acts upon this nucleus (just as we have in certain magneto-electric engines) so as to swell up the magnetism of the earth ultimately to saturation.[1]

May not this machinery be the great convection currents, the anti-trades, that go from the equator to the poles in the upper regions of the earth's atmosphere, and which may be looked on as conductors moving across lines of magnetic force?

It would appear to me that the tendency of such currents will be to swell up and sustain the magnetism of the earth.

(β) *Regarding the Diurnal and other Changes of Terrestrial Magnetism.*—It will of course be natural, entertaining the views now enunciated, to regard the diurnal changes of the convection currents of the earth's atmosphere, as these are manifested in the upper regions, to be the cause of the diurnal changes of terrestrial magnetism.

If this view be taken it might be argued that wind changes in these upper regions should also produce magnetic variations. The reply is that apparently they do. In conjunction with Mr. Morisabro Hiraoka I have compared together the simultaneous records of magnetic declination ranges at Kew and at Trevandrum, and I find evidence of a progress of things from west to east, so that on the whole a particular magnetic-range phenomenon occurs at Kew 9·7 days before it occurs at Trevandrum. Again, I have attempted to show, in conjunction with Mr. Dodgson, that a particular magnetic phenomenon occurs at Kew one day before it occurs at Prague.

It would thus appear that there is a progress of magnetic phenomena from west to east, just as we know there is a progress of meteorological phenomena. As, however, the meteorological phenomena which we can examine occur in the *lower* atmospheric regions, while the magnetic phenomena are, according to this hypothesis, associated with currents in the *higher* regions, it does not follow that magnetic and meteorological phenomena should travel from west to east at the same rate. I may also mention that we have reason to believe that magnetic changes lag behind corresponding solar changes just as meteorological changes would do.

It is manifest that it will be comparatively easy to settle the fact of a progress from west to east of magnetic weather, and that if such exists it will most readily ally itself with the hypothesis above mentioned.

In the next place, if we regard those changes in the convection-currents of the earth which depend on the year we have reason to imagine that such are most pronounced at the equinoxes. It is also well known that magnetic disturbances are most frequent at these times.

Let us next proceed to regard the secular change of the earth's magnetism. To account for this magneticians have felt the need of something movable, and the hypothesis of a "little earth," a solid nucleus moving within the recesses of our planet, has found much support. But is it not more likely that the result may be caused by a secular variation in the distribution of the convection-currents of the earth? If the question be asked, What reason have we for imagining the existence of such a variation, the answer will be, A much better reason than we have for entertaining the conception of a "little earth." For there is some reason, at any rate, for imagining the power of the sun to be subject to a complicated series of periodicities. Now a secular variation in the power of the sun would produce a secular change not only in the intensity, but in the direction of the convection-currents of the earth, and, according to the above hypo-

[1] If I am not mistaken Sir W. Thomson is inclined to regard the earth as a magneto-electric engine.

thesis, these in their turn would produce a secular magnetic change.

(γ) *Regarding Earth Currents and Auroras.*—I have for some considerable time looked on the earth as a Ruhmkorff's coil with a magnetic nucleus. Above this nucleus we may suppose that we have the primary rocks, which are non-conductors, while above these we have the moist or comparatively moist surface of the earth, which is a conductor. Above this, again, we have the lower strata of the atmosphere, which are non-conductors, while above this we have the upper strata, which are conductors.

Now suppose that a small but abrupt change of the earth's magnetism takes place, no matter how. We need not enter into the causes of such.

We have thus two secondary coils, if I may use the expression: (1) the moist surface of the earth, (2) the upper regions of the atmosphere; and both of these will be animated with secondary currents, on account of the abrupt change of the earth's magnetism. These secondary currents will be in one direction for a magnetic change of one kind, and in the opposite direction for a magnetic change of the opposite kind.

Now whenever there are magnetic storms, that is to say, when there are small but abrupt changes of the earth's magnetism, it is well known from the Greenwich records that we have violent earth currents, which are alternately positive and negative, and that we have also auroral displays in the upper regions of the earth's atmosphere. We cannot examine the auroral displays as we can the earth currents. But with regard to earth currents I would remark that the *form* of the phenomena they display is entirely against the supposition that such currents are the main cause of the changes in terrestrial magnetism, and in favour of that which maintains that they are secondary currents induced by magnetic changes.

In conclusion I would guard against its being supposed that all luminous appearances in the atmosphere are due to the same cause. I only hold that certain appearances which occur at times of magnetic perturbation and simultaneously throughout a large portion of the earth have the origin now mentioned.

B. STEWART

ON A NEW JELLY-FISH OF THE ORDER TRACHOMEDUSÆ, LIVING IN FRESH WATER

ON Thursday last, June 10, Mr. Sowerby, the secretary of the Botanical Society of London, observed in the tank in the water-lily house in Regent's Park a peculiar organism, of which he was kind enough to place a large number at my disposal on the following Monday.

The organism proves to be an adult medusa belonging to the order Trachomedusæ and the family Petasidæ of Haeckel's system ("System der Medusen," erster Theil). It comes nearest among described genera to Fritz Müller's imperfectly known *Aglauropsis* from the coast of Brazil.

The most obviously interesting matter about the form under notice is that it occurs in great abundance in perfectly fresh water at a temperature of 90° Fahr.

Hitherto no medusa of any order has been detected in fresh water—except perhaps some stray estuarine forms (? Crambessa).

It is exceedingly difficult to trace the introduction of this animal into the tank in the Regent's Park, since no plants have been recently (within twelve months) added to the lily-house, and the water is run off every year. Probably a few specimens were last year or the year before present in the tank, and have only this year multiplied in sufficient abundance to attract attention. Clearly this medusa is a tropical species, since it flourishes in water of the high temperature of 90° Fahr.

Mr. Sowerby has observed the medusa feeding on Daphnia, which abcunds in the water with it.

The present form will have to be placed in a new genus, for which I propose the name Craspedacusta, in allusion to the relation of its otocysts to its velum.

It is one of the sub-class Hydromedusæ or Medusæ craspedotæ, and presents the common characters of the order Trachomedusæ (as distinguished from the Narcomedusæ) in having its genital sacs or gonads placed in the course of the radial canals. It agrees with all Tracholinæ (Trachomedusæ and Narcomedusæ) in having endodermal otocysts, and it further exhibits the solid tentacles with cartilaginoid axis, the centripetal travelling of the tentacles, the tentacle rivets (Mantelspangen), the thickened marginal ring to the disk (Nessel ring) observed in many Tracholinæ.

Amongst Trachomedusæ, Craspedacusta finds its place in the Petasidæ, which are characterised as "Trachomedusæ with *four* radial canals, in the course of which the four gonads lie, with a long tubular stomach and no stomach-stalk."

Amongst Petasidæ it is remarkable for the great number of its tentacles, which are *all* solid; and for its very numerous otocysts. Further, it is remarkable among all Hydromedusæ (velate medusæ, that is, exclusive of Charybdæa) for the fact that centrifugal radiating canals pass from the otocysts *into the velum, where they end cæcally.*

The genus may be characterised as follows:—

MOUTH quadrifid, with four per-radial lobes.

STOMACH long, quadrangular, and tubular, projecting a good deal below the disk.

DISK, saucer-shaped, that is, flattened.

RADIATING CANALS 4, terminating blindly at the margin of the disk.

GONADS 4, in the form of 4 oval sacs, depending into the cavity of the subumbrella from the four radiating canals.

MARGINAL or RING CANAL obliterated (or if present of very minute size).

CENTRIPETAL CANALS (such as those of Olindias, Geryonia, &c.) absent.

TENTACLES solid; in three sets, which are placed in three superimposed horizons:—

1. A set nearest the aboral pole, of 4 large per-radial tentacles. These are the *primary* tentacles.
2. A second tier of (in large specimens) 28 medium-sized tentacles placed between these in four groups of seven. These are the *secondary* tentacles.
3. A third tier of (in large specimens) 192 small tentacles placed in groups of six between adjacent secondary tentacles. These are the *tertiary* tentacles.

TENTACLE-RIVETS (Mantel-spangen) connecting the roots of the tentacles with the marginal ring (Nessel-ring) are connected with all the tentacles of each of the three horizons.

OTOLITHS placed along the line of insertion of the velum—about eighty in number (fewer in small specimens). From sixteen to twenty are placed between successive per-radial tentacles arranged in groups of two or three between the successive secondary tentacles.

VELAR CENTRIFUGAL CANALS (which are really the elongated otocysts) are peculiar to this genus, passing from the otoliths (one inclosing each otolith) into the velum, and there ending blindly. They appear to correspond in character to the *centripetal* canals found in other Trachomedusæ in the disk.

OCELLI are absent.

[The presence of velar otocystic canals constitute the chief peculiarity of the genus Craspedacusta, and may necessitate the formation of a distinct family or sub-order for its reception. The minute structure of the otoliths and canal-like otocysts I am now engaged in investigating.]

The above characters are derived from the examination of *adult* male specimens, which were freely discharging ripe, actively motile spermatozoa.

The species may be known as CRASPEDACUSTA SOWERBII, nov. gen. et sp.—I name the species in honour of Mr. Sowerby, who discovered it, and to whose quick observation and courteous kindness zoologists are indebted for the knowledge of this interesting animal.

The sole character which I can give as specific over and above the generic characters summarised above is that of size. The diameter of the disk does not exceed one-third of an inch.

Locality.—The water-lily tank in the gardens of the Botanical Society, Regent's Park, London.

Very abundant during June, 1880. Probably introduced from the West Indies. E. RAY LANKESTER

NOTES FROM JAVA

THE following extracts from a letter written from Java by Mr. Henry O. Forbes to Mr. H. N. Moseley, F.R.S., have been sent to us for publication as of considerable interest. The letter is dated March 19. Mr. Forbes, who has been engaged in collecting in Java, expects shortly to leave for Celebes, Timor, Timor-laut, and other eastern islands. Timor-laut is the most important island of the Malay Archipelago yet remaining to be explored, and is likely to yield many natural history treasures. Mr. Forbes's letter refers to certain passages in Mr. Moseley's "Notes by a Naturalist on the *Challenger*." The question of the mode of growth of Myrmecodia and Hydrophytum has been lately before the Linnean Society.

"With regard to birds carrying seeds from one island to another, I have observed on the Cocos Keeling Islands (South Indian Ocean) a species of heron which nested in a high tree (species unknown) there, quite covered with its oblong hooked seeds. I was informed by the proprietor of the island that many of these birds, from their feathers getting so thickly covered with the seeds, actually die. I can therefore imagine that many of these seeds might adhere for even *weeks and months*, and so get transported to very distant regions.

"At p. 493 you note the habit of hot-water drinking. It is quite a custom among, at any rate, the Sudanese, among whom I have been living some time, who, in the afternoons, invite each other to come and have a cup of hot water. It is drunk either plain or with a little arenga sugar.

"I have found here a large quantity of algæ growing in the hot springs at a temperature of 132° F. What the species are or is I have not yet ascertained.

"With reference to Myrmecodia and Hydnophytum, I find some difficulty in reconciling in all cases the statement (p. 389) that 'the ants gnaw at the base of the stem, and the irritation produced causes the stem to swell,' with what I have myself observed. I have grown many young seedlings, some of which were entirely unmolested by ants, and yet produced a bulbous swelling at the base; others were certainly scratched, but that was all, by the ants, the smallest scar being visible. On opening many of those which were unmolested I observed a degenerated, soft, spongy portion, not in connection with the exterior. May not this spot increase till an external opening is formed, and the ants have an entrance made for them to carry out, as I have seen them doing, the soft spongy substance inside? I have seen other seedlings that had a small orifice close to the rootlet, leading into an interior oval or round expansion in the bulb, and though I closely observed them I failed to detect ants touching them. All these seedlings I grew from the seed till they reached at most a couple or three inches or a little more, when they generally became the home of some ants. After they had become infested I did not pursue observations on them, as my time was much occupied, and because the object of my observation was to discover if they bulbed, &c., without the aid of ants. I should much like to see these plants grow with all ant life removed from them entirely. If opportunity again offers I shall continue my experiments. I have repeatedly noticed on large Myrmecodia and Hydnophyta which were crowded with ants (on both genera I have found only one species of ant) that in many places irregularly-shaped areas of degeneration existed quite cut off from communication with the wonderful series of galleries and chambers which form this ant-hive. These were found oftenest near the upper portion of the bulb, and towards which excavations were being directed. I have not observed that the surface of the rounded mass gives off any twigs bearing leaves or flowers. All my specimens have had the shape of a bulb more or less gobose, or elongate, prickly, tenanted by ants, giving origin to a much thinner stem, not, or rarely, chambered nor passaged, but also armed, and from which the leaves and sessile flowers proceeded, the latter from hollows in which numerous ants were constantly moving about. The Hydnophyta generally give off at once leaves at the summit of a more or less irregular bulb.

"I have seen the same species of ant inhabiting the swollen-up hollow leaves of a species of Hoya or Æschynanthus. The plant I saw had many of its leaves in this condition. I gathered it one day while on the march, and I fear it is lost. It *may* have been sent to the British Museum, but I am not certain. I have not met with another instance. There was a small hole in the apex of the leaf, and through it the ants came and went. The leaf looked as if all the mesophyllum had been cleared out and the epidermis blown out into a bladder. This observation may not be quite accurate as to the description of leaf, but I noted that the species of ant was the same.

"Here it is quite impossible to obtain a perfect rhinoceros skull, unless one has the good fortune to shoot it oneself, for the horn is so highly prized that it alone fetches from 200 to 300 rupees (Dutch guelders), being eagerly bought by the Chinese. It is believed in by all the natives as a sure and certain antidote for snake-bites and for purifying water. A respectable hadji affirmed to me with the persistency of belief that on his way to Mecca —he went in a native vessel—the stock of fresh water on board ran out, and that all on the vessel, by drinking sea-water out of a rhinoceros horn, found it to be—not salt water!"

ON THE FERTILISATION OF COBÆA PENDULIFLORA (HOOK. FIL.)

COBÆA PENDULIFLORA is a graceful climber, growing rather sparingly in our mountain-forests. It was described and figured by Karsten under the name of *Rosenbergia penduliflora* ("Flora Columbiæ," I. 27, t. ix.), and afterwards in the *Bot. Mag.*, i. 5757. Karsten's plate is very pretty, but in all the specimens I have seen the linear lobes of the corolla were never so red as he paints them, nor do the stamens ever hang straight downwards parallel to the style, as his figure shows. The plate in the *Botanical Magazine* has only one defect, the artist having overlooked the hooklets and the ends of the tendrils.

The plant grows exceedingly quickly when kept in shade. A specimen now in my garden was raised from seed sown October 3, 1879, which sprang up a fortnight later, and covered, in less than three months, a wall twelve feet high and ten feet long. It climbs exactly in the same manner as *Cobæa scandens*, described by Darwin in his "Climbing Plants." The flowers have very little to attract attention, their colour being dull green, with very little red on the filaments, and there is no smell. Though not of great horticultural interest, the plant fully deserves the attention of the botanist on account of the peculiar circumstances under which the flowers are fertilised. Sir J. D. Hooker has made already some pertinent remarks on

this point in his description in the *Bot Mag*, and it was for the further investigation of the case that I raised a plant in my garden

The flowers grow on long peduncles, which generally have a horizontal position, projecting some five or six inches from the mass of the foliage When the calyx opens, the filaments as well as the style are irregularly twisted; but in about two or three days all become straight. The style hangs obliquely downwards, the filaments all bend sideways, the bend being inside the tube of the corolla, a little over the hairs at their base There is often a distance of 15 centimetres between the anthers of either side. About 5 or 6 o'clock p m the anthers burst, and soon after the style rises and assumes a central position, so that there is a distance of about 10 centimetres between the stigmata and any of the anthers *Only then* is nectar being secreted by the glandular disk round the base of the ovary, but so copiously that by means of a small pipette I obtained from each flower a mean quantity of 0 14 cubic centimetres This nectar is completely transparent very sweet, and slightly mucilaginous. It contained a kind of gum which is precipitated by absolute alcohol. *The nectar appears therefore when the anthers have done their work*, even an hour before their rupture no trace of it is to be found The nectar cavity in the tube of the corolla is completely shut up by the numerous spreading hairs at the base of the filaments, so that an outflow is impossible The grains of pollen are very large (0 2 millim. in diameter) and of the same structure as in *Cobæa scandens* They are covered by a glutinous layer, and are heavier than water

Several weeks passed at first before I witnessed the manner of fertilisation The stigmata were every morning carefully examined, but no pollen could be discovered on them The filaments twisted back again and got somewhat frizzled after one single night s expansion About noon the corolla drops off separating from close to the glandular ring and then slipping down over the style which by this time, is again in a relaxed hanging position There is always some nectar in the tube of the corolla after its separation, but none remains in the calyx round the ovary, nor does its secretion continue

These facts show clearly that the fertilisation must take place in the same night after the bursting of the anthers, and it was but natural to suppose that it was effected by nocturnal moths It would appear, furthermore, that *the nectar is not of any direct advantage to the plant*, as Mr G Bonnier emphatically affirms (*Annales des Sci Nat Bot*, sér vi vol viii p 206), because of its being produced and lost in all flowers, fertilised or not, in the same way

As soon as the number of flowers increased (on some evenings twenty to twenty five had their anthers opened), I found every morning most of them with pollen on the stigmata, and keeping a close watch, I discovered that the plant was visited by several large Sphingidæ belonging to the genera *Chaerocampa*, *Diludia* and *Amphonyx* I observed altogether four visits of an Amphonyx, three of a Chaerocampa, and one of a Diludia All of them proceeded in the same manner Holding the body close over the style, they dipped their spiral tongues into the tube of the corolla, beating all the while the anthers so violently with the tips of the fore-wings that they dangled about with great velocity in every direction The grains of pollen being covered by a sticky substance, many of them adhered to the wings. I have caught an Amphonyx which, after having visited six flowers consecutively, had the tips of the fore-wings almost yellow with pollen When leaving a flower for another one, some of this pollen is even lost on the foliage, but by the time the insect takes its central position before the flower the stigmata are likewise touched by the wings and thus some pollen is left on them Some flowers remain without being fertilised, especially in places where the moths cannot reach them easily All flowers fertilised in this manner set fruit very soon; but no flower gave a fruit without having its stigmata pollenised by crossing

Self-fertilisation is therefore excluded, and this is further proved by the following experiments —Twelve flowers were artificially fertilised by their own pollen and afterwards protected by muslin bags, only in one case was a fruit obtained, but I am not quite sure whether there did not come some foreign pollen on the stigmata of this flower Cross fertilisation was likewise tried in twelve flowers, nine being experimented on in the same evening after the opening of the anthers, and three the next morning. All the former are now with fruit, the latter remained sterile. This fact shows how very short is the period of possible fertilisation.

Flowers visited by nocturnal moths are as a rule either large and of white colour, or have a strong smell, but in our *Cobæa* the former is certainly not the case, and my olfactory nerves at least cannot discover any smell But it is well known that insects, especially Lepidoptera, are in this respect of a really wonderful keenness, which enables them to track a scent absolutely imperceptible to man.

As I shall have a considerable crop of Cobæa seeds, I can offer some to any botanists who should wish to grow the plant A Ernst

Carácas, April 4

P S —As soon as the corolla has fallen off the peduncle withdraws slowly amongst the dense foliage, where the fruit develops, protected from all kinds of injury

EXPERIMENTAL RESEARCHES IN ELECTRICITY[1]

Part III —*Tube Potential, Potential at a Constant Distance and Various Pressures, Nature and Phenomena of the Electric Arc*

MESSRS De la Rue and Muller in the third part of their researches on the electric discharge, commence by describing a series of experiments to determine the potential necessary to produce a discharge in a tube exhausted gradually more and more while using a constant number of cells in all the experiments In consequence of the life of the battery becoming so much exhausted by the method employed the experiments were confined to one gaseous medium, namely, hydrogen Since the completion, however, of the measurements described in the paper the authors have found two other more convenient methods for determining the tube potential, which do not exhaust the battery injuriously these are described in an appendix The tube, 162, employed was 33 inches long and 2 inches in diameter, the distance between the ring and straight wire terminals being 29 75 inches the battery consisted of 11,000 cells The discharge took place when the pressure was reduced to 35 5 mm, 46,710 M (millionths of an atmosphere), and the exhaustion was afterwards continued gradually until it fell to 0 0065 mm 8 6 M In commencing each set of experiments the deflection of a tangent-galvanometer was observed when the battery was short circuited By a table previously calculated the value of the deflection in ohms of resistance per cell could be read off, this, multiplied by 11,000, gave the total resistance of the battery the tube was then connected with the terminals and the galvanometer again observed this gave a less deflection and indicated a greater resistance, which, multiplied by 11,000, gave the total resistance of the tube and battery by subtracting the resistance of the battery the resistance of the tube was ascertained Calling the total resistance R the tube resistance r, the tube potential V, $V = \frac{r \times 11{,}000}{R}$ The tube potential requisite to produce a discharge with a pressure of 46,710 M was found to be 10 250 cells; this gradually fell until

[1] Experimental Researches on the Electric Discharge with the Chloride of Silver Battery by Warren De la Rue M A. D C.L F R S and Hugo W Müller Ph D F R S (*Phil Trans* vol clxxi p 65)

a pressure of 0·642 mm., 1,082 **M**, was reached, the tube-potential being then only 430 cells, after which it rapidly rose, and, at 8·6 **M**, it required a potential of 8,937 cells to produce a discharge. From the experiments described

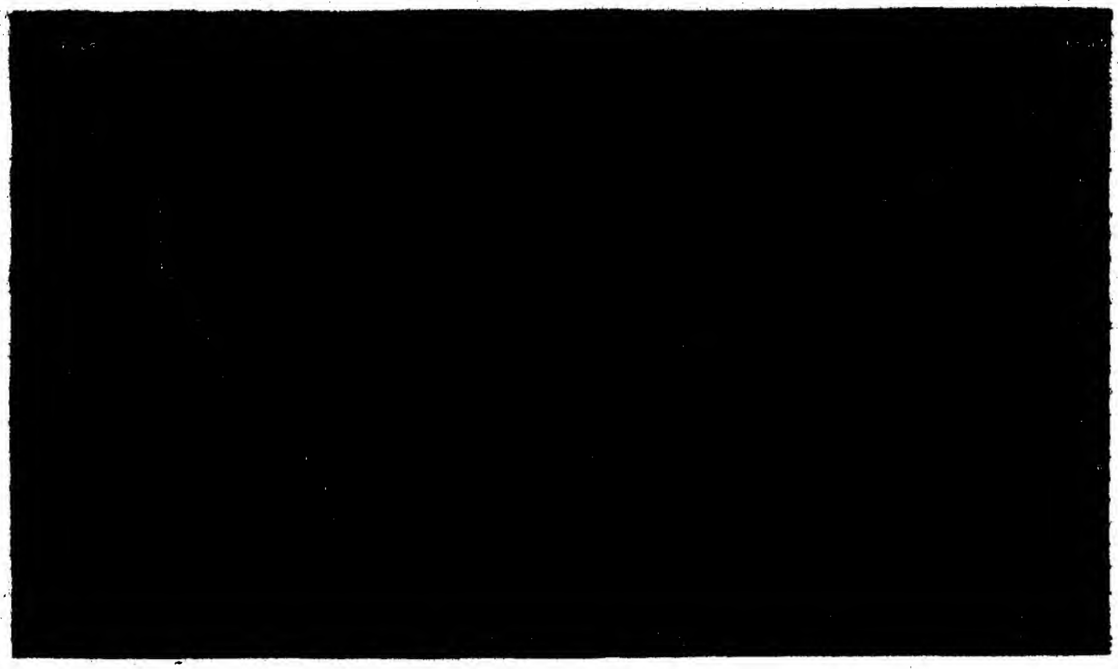

DIAGRAM I.

in a previous paper it was found that, in another tube, it required the full potential of 11,000 cells to produce a discharge at 3 **M**, and that, at 1·8 **M**, this potential was insufficient. The obstruction to the discharge in tube

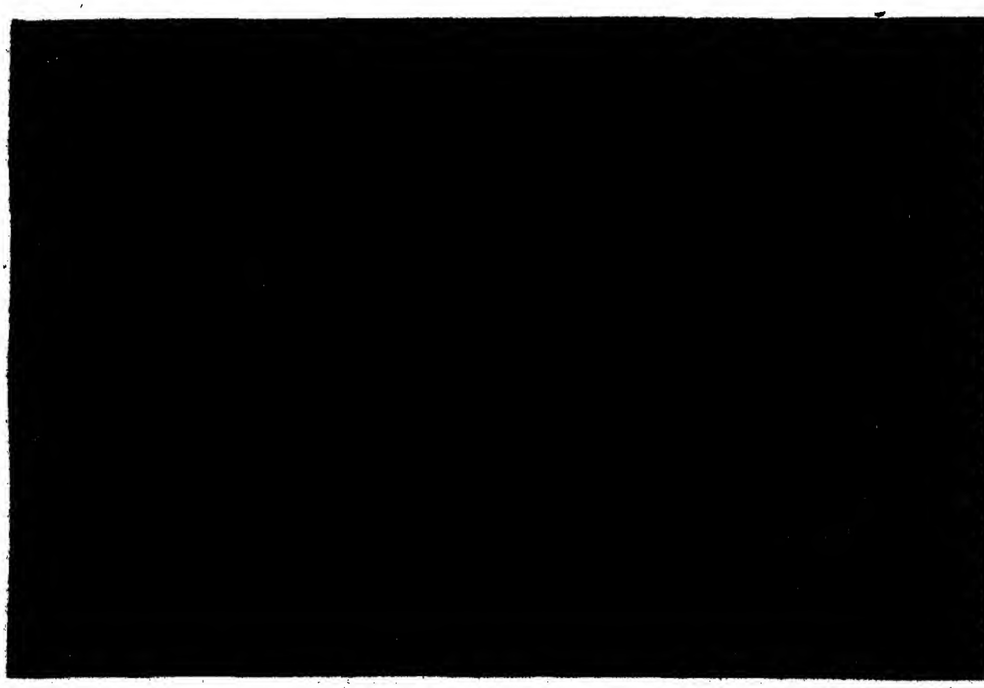

DIAGRAM II.

A—B represents an assumed mean distance of the molecules at a pressure of 5 millionths of an atmosphere. A′ to 10, A′ to 20, ... A′ to 40960, the corresponding distances at pressures 10, 20, 40960 millionths.

162 was as great at 8·6 **M** as at 28,553 **M** pressure, and required 8,950 cells in each case.

The diagram (No. I.) laid down from the results when the ring was made positive, shows the curve of the obser-

vations as actually obtained without being smoothed. The figure is a reduction to $\frac{1}{8}$ of the original; the abscissæ are as the cube-roots of the various pressures in millionths of an atmosphere, and show relatively the number of molecules in a given linear space; the ordinates are as the number of cells.

The observations were again plotted down as in Diagram No. II., making the abscissæ in the inverse ratio of the cube-roots of the various pressures in millionths, so as to represent relatively the mean distance of the molecules at the various pressures in millionths of an atmosphere; this has the effect of extending the scale for decreasing pressures beyond the minimum resistance of the tube, and of compressing it on the opposite side for increasing pressures.

The following tables show the number of cells necessary to produce a discharge for various pressures in millionths of an atmosphere :—

An experiment was made in order to ascertain whether there was either any condensation or dilatation of the gas in contiguity with the terminals before the actual passage of the discharge. In order to do this an apparatus was constructed, as shown in Fig. 1.

It consists of a glass cylinder, 4·35 inside diameter, the depth of which is accurately the same in every part, 1·6 inch, so as to insure the parallelism of two glass disks which close its ends. Its cubical contents exclusive of the terminals was found to be 385 cub. centims.

These are held in contact with the ends of the cylinder by means of screw-clamps made of ebonite, and the whole apparatus is supported on a tripod ebonite stand, which is fastened to a square wooden foot. Attached parallel to the top and bottom glass disks, by means of flanged-screw rods, are two brass disks with rounded edges, 3·1 inches in diameter; these are maintained at a distance of 0·13 inch, 3·3 mm. at which the discharge of 11,000 cells would only just take place.

The ends which project through the glass disks are furnished with binding-screws for attaching wires from the battery.

On the side of the cylinder is a tubulure in which is fitted a gauge containing strong sulphuric acid, so as to dry the inside of the apparatus, and to indicate whether any condensation or dilatation of the gas contained in the cylinder occurs on connecting the metallic disks with the battery by means of the contact-key. The edges of the cylinder were rubbed with grease, and care was taken to prove that the apparatus was perfectly tight by causing the fluid in the limb of the gauge to stand for some time higher than that in the bulb. When connection was made with a battery of 9,800 cells, there was not the slightest indication of any alteration of volume of the contained air, so that there was neither condensation about the disks which would have caused a contraction, nor repulsion from the disks which would have caused an expansion of volume. The fluid in the stem was observed with a lens, but not the slightest motion of it took place. The same result was noticed even when water was substituted for sulphuric acid. So far, then, as this apparatus would indicate it, the result is entirely negative.

Potential necessary to produce a discharge between disks 1·5 inch diameter at a constant distance and at various pressures

The experiments were made by placing the micro-

meter-discharger, shown in Fig. 2, under the bell-jar of an air pump to which was attached a gauge about 36 inches long in order to indicate the pressure of the contained gas. In the first instance the disks were adjusted to the striking-distance at atmospheric pressure for the battery of 11,000 cells. Afterwards a less number of cells was connected with the disks and the bell-jar gradually exhausted until the discharge occurred; the height of the mercury in the gauge was then read off. Then a less and less number of cells was connected with the disks and the operation was repeated.

In air the discharge took place at ordinary atmospheric pressure with 11,000 cells when the disks were 0·13 inch, 3·3 mm. distant, and with 600 cells at an average pressure of 10 mm.

In hydrogen it took place at atmospheric pressure with 11,000 cells when the disks were 0·22 inch, 5·59 mm. distant; and with 600 cells at an average of 14 mm. pressure.

In carbonic acid, at atmospheric pressure with 11,000 cells, when the disks were 0·122 inch, 3·096 mm. distant; and with 600 cells at an average pressure of 5·2 mm.

The numbers obtained for air, hydrogen, and carbonic acid respectively were plotted down on millimetre scale paper, the abscissæ being 1 mm. = 2,500 M, the ordinates 1 mm. = 25 cells, and curves drawn to give a mean of the several observations. These appeared to resemble hyperbolic curves so closely that true hyperbolic curves were found partly by a geometric construction, partly by computation, which would intersect the mean experimental curves in two points. The results of experiment were again laid down on these new curves, and it was found that they did not differ more from them than they did from each other.

The ratio of the transverse axis (pressure) to the conjugate axis (potential) of the hyperbolas set out on the above-mentioned scale was—

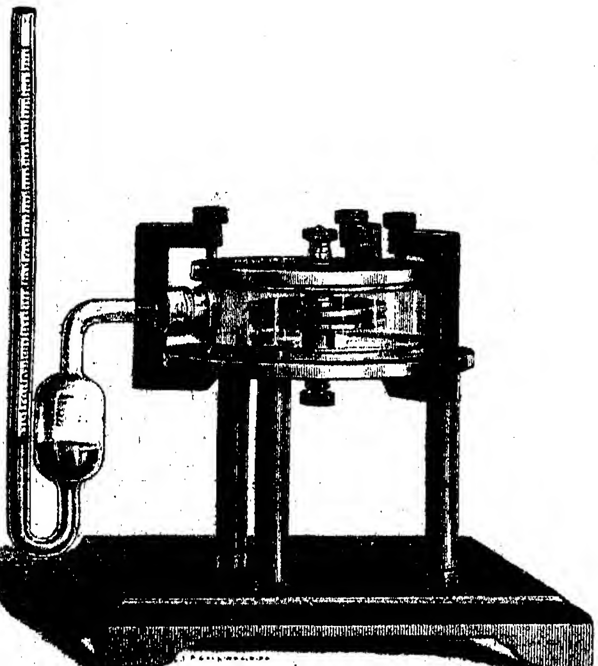

Fig. 1.

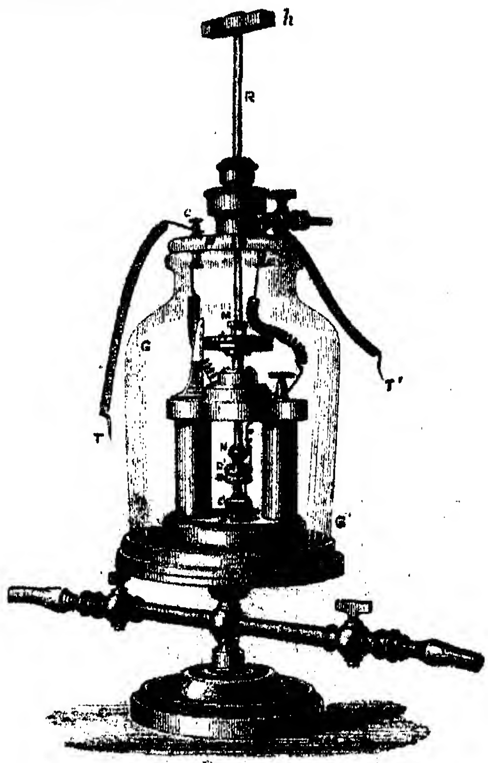

Fig. 2.

For air	0·9665
„ hydrogen	1·0170
„ carbonic acid	1·0690

The striking distances at atmospheric pressure for spherical surfaces 3 inches radius and 1·5 inch diameter, with various potentials, as given in Part I. page 68, curve VIII. and at page 118, also those for nearly flat surfaces in pages 73 and 118, were reduced to millimetres distance and plotted down in the same way, but not on precisely the same scale as the preceding curves for constant distance and various pressures. Hyperbolic curves were also found which intersected the experimental curves in two points.

It was seen in the case of spherical surfaces, the result having been obtained as the average of a great number of experiments, that the hyperbola coincided closely with the observations, while for plane surfaces, for which only a few experiments were made, the coincidences were not quite so perfect. Nevertheless, it would appear that the law of the hyperbola holds equally well for a constant pressure and varying distance as it does for a constant distance and varying pressure; the obstacle in the way of a discharge being up to a certain point as the number of molecules intervening between the terminals.[1]

In the two cases of spherical and plane surfaces the ratio between the transverse (distance) and conjugate (potential) axes of the respective hyperbolas was—

For spherical surfaces	1·240
„ disks	1·285

With the data already published in Part I., the authors have laid down a fresh curve for the striking distance

[1] Dr. Alexander Macfarlane has published in the *Transactions* of the Royal Society of Edinburgh, 1878, vol. xxvii., an elaborate and careful research of the "Disruptive Discharge of Electricity" in air and different gases, and between terminals of various forms. An abstract of this paper will be found in NATURE, vol. xix. pp. 184, 185. Dr. Macfarlane used a Holtz machine and employed higher potentials than those we used; he found that the results for the discharge between two disks 4 inches in diameter at various distances up to 1·2 centims. and with various pressures were satisfactorily represented by the hyperbola.

between flat disks on a scale of 10 centims. for a millimetre and 5 centims. to 1,000 cells.

From the curve thus laid down the following numbers were deduced:—

EMF in volts.	Striking distance in centimetres.	Difference of potential per centimetre.	Intensity of force.	
			Electro-magnetic.	Electro-static.
		volts.		
1,000	0·0205	48,770	4·88 × 10¹²	163
2,000	0·0430	46,500	4·65 ,,	155
3,000	0·0660	45,450	4·55 ,,	152
4,000	0·0914	43,770	4·38 ,,	146
5,000	0·1176	42,510	4·25 ,,	142
6,000	0·1473	40,740	4·07 ,,	136
7,000	0·1800	38,890	3·89 ,,	130
8,000	0·2146	37,280	3·73 ,,	124
9,000	0·2495	36,070	3·61 ,,	120
10,000	0·2863	34,920	3·49 ,,	116
11,000	0·3245	33,900	3·39 ,,	113
11,309	0·3378	33,460	3·35 ,,	112

The remainder of the paper is chiefly occupied with the study of the phenomena of the electric arc under various conditions of distance, pressure, and potential; the results obtained support the view that the arc and the stratified discharge are merely modifications of the same phenomenon.

(To be continued.)

A FOURTH STATE OF MATTER[1]

IN introducing the discussion on Mr. Spottiswoode and Mr. Moulton's paper on the "Sensitive State of Vacuum Discharges," at the meeting of the Royal Society on April 15, Dr. De La Rue, who occupied the chair, good-naturedly challenged me to substantiate my statement that there is such a thing as a fourth or ultra-gaseous state of matter.

I had no time then to enter fully into the subject; nor was I prepared, on the spur of the moment, to marshal all the facts and reasons which have led me to this conclusion. But as I find that many other scientific men besides Dr. De La Rue are in doubt as to whether matter has been shown to exist in a state beyond that of gas, I will now endeavour to substantiate my position.

I will commence by explaining what seems to me to be the constitution of matter in its three states of solid, liquid, and gas.

I. First as to Solids:—These are composed of discontinuous molecules, separated from each other by a space which is relatively large—possibly enormous—in comparison with the diameter of the central nucleus we call *molecule*. These molecules, themselves built up of *atoms*, are governed by certain forces. Two of these forces I will here refer to—attraction and motion. Attraction when exerted at sensible distances is known as *gravitation*, but when the distances are molecular it is called *adhesion* and *cohesion*. Attraction appears to be independent of absolute temperature; it increases as the distance between the molecules diminishes; and were there no other counteracting force the result would be a mass of molecules in actual contact, with no molecular movement whatever—a state of things beyond our conception—a state, too, which would probably result in the creation of something that, according to our present views, would not be *matter*.

This force of cohesion is counterbalanced by the movements of the individual molecules themselves, movements varying directly with the temperature, increasing and diminishing in amplitude as the temperature rises and falls. The molecules in solids do not travel from one part to another, but possess adhesion and retain fixity of position about their centres of oscillation. Matter, as we know it, has so high an absolute temperature that the movements of the molecules are large in comparison with their diameter, for the mass must be able to bear a reduction of temperature of nearly 300° C. before the amplitude of the molecular excursions would vanish.

The state of solidity, therefore—the state which we are in the habit of considering *par excellence* as that of *matter*—is merely the effect on our senses of the motion of the discrete molecules among themselves.

Solids exist of all consistences, from the hardest metal, the most elastic crystal, down to thinnest jelly. A perfect solid would have no viscosity, *i.e.*, when rendered discontinuous or divided by the forcible passage of a harder solid, it would not close up behind and again become continuous.

In solid bodies the cohesion varies according to some unknown factor which we call chemical constitution; hence each kind of solid matter requires raising to a different temperature before the oscillating molecules lose their fixed position with reference to one another. At this point, varying in different bodies through a very wide range of temperature, the solid becomes liquid.

II. In liquids the force of cohesion is very much reduced, and the adhesion or the fixity of position of the centres of oscillation of the molecules is destroyed. When artificially heated, the inter-molecular movements increase in proportion as the temperature rises, until at last cohesion is broken down, and the molecules fly off into space with enormous velocities.

Liquids possess the property of viscosity—that is to say, they offer a certain opposition to the passage of solid bodies; at the same time they cannot permanently resist such opposition, however slight, if continuously applied. Liquids vary in consistency from the hard, brittle, apparently solid pitch to the lightest and most ethereal liquid capable of existing at any particular temperature.

The state of liquidity, therefore, is due to inter-molecular motions of a larger and more tumultuous character than those which characterise the solid state.

III. In gases the molecules fly about in every conceivable direction, with constant collisions and enormous and constantly varying velocities, and their mean free path is sufficiently great to release them from the force of adhesion. Being free to move, the molecules exert pressure in all directions, and were it not for gravitation they would fly off into space. The gaseous state remains so long as the collisions continue to be almost infinite in number, and of inconceivable irregularity. The state of gaseity, therefore, is pre-eminently a state dependent on collisions. A given space contains millions of millions of molecules in rapid movement in all directions, each molecule having millions of encounters in a second. In such a case the length of the mean free path of the molecules is exceedingly small compared with the dimensions of the containing vessel, and the properties which constitute the ordinary gaseous state of matter, which depend upon constant collisions, are observed.

What, then, are these molecules? Take a single lone molecule in space. Is it solid, liquid, or gas? Solid it cannot be, because the idea of solidity involves certain properties which are absent in the isolated molecule. In fact, an isolated molecule is an inconceivable entity, whether we try, like Newton, to visualise it as a little hard spherical body, or, with Boscovich and Faraday, to regard it as a centre of force, or accept Sir William Thomson's vortex atom. But if the individual molecule is not solid, *à fortiori* it cannot be regarded as a liquid or gas, for these states are even more due to inter-molecular collisions than is the solid state. The individual mole-

[1] "On a Fourth State of Matter," in a letter to the Secretary of the Royal Society. By W. Crookes, F.R.S.

cules, therefore, must be classed by themselves in a distinct state or category.

The same reasoning applies to two or to any number of contiguous molecules, provided their motion is arrested or controlled, so that no collisions occur between them; and even supposing this aggregation of isolated non-colliding molecules to be bodily transferred from one part of space to another, that kind of movement would not thereby cause this molecular collocation to assume the properties of gas; a molecular wind may still be supposed to consist of isolated molecules, in the same way as the discharge from a mitrailleuse consists of isolated bullets.

Matter in the fourth state is the ultimate result of gaseous expansion. By great rarefaction the free path of the molecules is made so long that the hits in a given time may be disregarded in comparison to the misses, in which case the average molecule is allowed to obey its own motions or laws without interference; and if the mean free path is comparable to the dimensions of the containing vessel, the properties which constitute gaseity are reduced to a minimum, and the matter then becomes exalted to an ultra-gaseous state.

But the same condition of things will be produced if by any means we can take a portion of gas, and by some extraneous force infuse order into the apparently disorderly jostling of the molecules in every direction, by coercing them into a methodical rectilinear movement. This I have shown to be the case in the phenomena which cause the movements of the radiometer, and I have rendered such motion visible in my later researches on the negative discharge in vacuum tubes. In the one case the heated lamp-black and in the other the electrically excited negative pole supplies the *force majeure* which entirely or partially changes into a rectilinear motion the irregular vibration in all directions; and according to the extent to which this onward movement has replaced the irregular motions which constitute the essence of the gaseous condition, to that extent do I consider that the molecules have assumed the condition of radiant matter.

Between the third and the fourth states there is no sharp line of demarcation, any more than there is between the solid and liquid states, or the liquid and gaseous states; they each merge insensibly one into the other. In the fourth state properties of matter which exist even in the third state are shown *directly*, whereas in the state of gas they are only shown *indirectly*, by viscosity and so forth.

The ordinary laws of gases are a simplification of the effects arising from the properties of matter in the fourth state; such a simplification is only permissible when the mean length of path is small compared with the dimensions of the vessel. For simplicity's sake we make abstraction of the individual molecules, and feign to our imagination *continuous* matter of which the fundamental properties—such as pressure varying as the density, and so forth—are ascertained by experiment. A gas is nothing more than an assemblage of molecules contemplated from a simplified point of view. When we deal with phenomena in which we are obliged to contemplate the molecules individually, we must not speak of the assemblage as *gas*.

These considerations lead to another and curious speculation. The molecule—intangible, invisible, and hard to be conceived—is the only true *matter*, and that which we call matter is nothing more than the effect upon our senses of the movements of molecules, or, as John Stuart Mill expresses it, "a permanent possibility of sensation." The space covered by the motion of molecules has no more right to be called matter than the air traversed by a rifle bullet can be called lead. From this point of view, then, matter is but a mode of motion; at the absolute zero of temperature the inter-molecular movement would stop, and although *something* retaining the properties of inertia and weight would remain, *matter*, as we know it, would cease to exist.

NOTES

THE Council of the Society of Arts have awarded the Albert Medal of the Society of the present year to James Prescott Joule, LL.D., D.C.L., F.R.S., "for having established, after most laborious research, the true relation between heat, electricity, and mechanical work, thus affording to the engineer a sure guide in the application of science and industrial pursuits." The medal was delivered to Dr. Joule by the Prince of Wales on Tuesday, when Sir William Thomson received the medal awarded him by the Society in 1878.

THE Paris Academy of Sciences has awarded the Monthyon Prize to M. Camille Flammarion for his new work entitled "Astronomie Populaire." It is a large 4to volume, with magnificent engravings, which was sold in 100 penny parts. The sale in the first year of publication reached 40,000 copies.

IT is stated that M. Coggia, Astronomer to the Marseilles Observatory, will be appointed Director of the Algiers Observatory, where no observations at all have been made since its creation in 1864 by Marshal Pelissier.

THE University of Oxford has conferred the degree of D.C.L on Prof. Sylvester and Mr. Lister, the eminent surgeon.

ON Saturday, May 5, the local committee of the French Association for the Advancement of Science met at Rheims, where the next meeting is to be held in August. An exposition of local industry and archæology will be held. Arrangements have been made for excursions connected with the congress, the more notable of which will be to the Han Grottoes, which are situated in Belgium. Nothing has been arranged yet as to the lectures to be delivered.

THE new Principal of the Royal Agricultural College, Cirencester, the Rev. J. B. McLellan, has started a scheme of congresses or conferences which may prove of considerable value to agriculture. On Friday, the 5th inst., a goodly number of old Cirencester students and professors, as well as local agriculturists, met in the College Hall to discuss important agricultural questions. The morning session was occupied with the subject of cattle diseases; the afternoon was devoted to agricultural stations and research. If the papers introducing the subjects were not of a very high order, it may at least be conceded that the discussions which followed brought out some sound information and advice. If such congresses as this at Cirencester help to draw public attention to the need for some new departure in modern and scientific agriculture, and if they stimulate those interested in farming to look to the College as the central authority on a subject which that institution must learn to handle adequately, then we predict for them a substanial success.

THE annual conference at the Society of Arts on the laws, administration and inspection with regard to public health was opened on Thursday under the presidency of Mr. Stansfeld, M.P. The committee had drawn up a programme of subjects for discussion, which were grouped under the following headings:—1. Administrative Organisation: 2. Amendment of the Law: 3. Sanitary Inspection and Classification of Dwellings: 4. Further suggestions by Sanitary Authorities. In the discussion on Thursday the chairman, in opening the proceedings, pointed out the desirability of an "inquiry office" being established in connection with the Local Government Board, at which local authorities might obtain information based on experience. One great hope for the future was that the teaching of the laws of health to children was gradually spreading. The conference was resumed on Friday. In reference to the third heading, the following resolution was put to the meeting:—"That it is expedient that the Metropolitan Board of Works within the metropolis, and the County Board within each county, should

be empowered by the Legislature to make provision for the inspection and sanitary classification of dwellings, upon application being made by the owners thereof, and to grant certificates of healthworthiness in different categories, for terms of years, according to the perfection of sanitary equipment and fitness for habitation of such dwellings; and to determine the scale of fees to be paid for such inspection during construction and repair, and also upon delivery to the applicant of the certificate of classification awarded to such dwelling. In the long discussion which followed it was clear that the sense of the conference was in favour of some change, but opinions were much divided as to how inspection and certificates should be brought to bear. Among other arguments it was urged that, as Lloyd's Association inspected the construction of ships and granted certificates, it would be only an extension of a recognised system to inspect and give certificates for houses. After a protracted discussion, the resolution was passed with some few alterations. An exhibition of sanitary appliances was open free to the public. The chief novelty was the new filtering medium adopted by the Admiralty and War Office named Carferal, on which Prof. De. Chaumont has recently reported so favourably.

MR. R. L. JACK, the Government Geologist of Queensland, has been carrying out his survey operations under difficulties unknown to home geologists. While he and his party were pursuing their explorations in the north of York Peninsula they were attacked by a band of natives, Mr. Jack receiving a spear in the neck, which had to be cut out. Fortunately the wound, though troublesome, is not likely to be attended with any serious or permanent results. North of Temple Bay Mr. Jack came upon a hitherto unknown large river, which he has named the "Macmillan."

THE *Daily News* gives some account of a recent lecture by Prof. Palmieri on earthquakes. Prof. Palmieri went on to say that earthquakes have no doubt shorter or longer periods of preparation. The earth is never perfectly quiet for some time before and after a great shock, but gradually sinks into repose or increases in agitation. The Professor believes that, by registering the slight preliminary tremblings and noticing their increase or decrease it would be possible to forestall an earthquake about three days in advance, just as tempests are now foretold. If a connected system of seismographic stations were to be organised —the different stations communicating with each other by telegraph—it would be quite possible, in most cases, to issue warnings to the threatened district in time. The seismographic stations should be erected by the different Governments in quiet places where the ground was not liable to be shaken by heavy railway trains.

THE illumination of the park of the Industrial Exhibition of Melun with Wild candles has been considered successful, and will be continued every night during the whole of the summer. It is said that the proprietors of the Wild patent will take an injunction against M. Jamin for an infringement of their patent, alleging that his directing frame is not an independent invention.

M. W. DE FONVIELLE has discovered that the intermittent current of the frame of his electro-magnetic gyroscope can be made continuous if the magnet is replaced by an electro-magnet worked by an interrupter.

THE French Government has taken an important step in the education of the people; a course of teaching in agriculture has been ordered to be introduced into every primary school in the country.

MESSRS. MACMILLAN AND CO. have published a sixth edition of the late Prof. George Wilson's well-known little book, "The Five Gateways of Knowledge."

CHEMISTS engaged in the analysis of alcoholic liquids will be able shortly to possess an elaborate and complete series of tables of spirit gravities, prepared by Dr. Thos. Stevenson, of Guy's, and to be published in handy book size by Mr. Van Voorst.

MR. G. AMBROSE POGSON, British Vice-Consul at Hamburg, writes to the *Times* from that place, under date June 12, as to "St. Elmo's Fire":—A series of thunderstorms, he states, has lately passed over Hamburg. During the 11th inst. the air was densely charged with electricity; the storm broke about 10.15 p.m., lasting until 11 p.m., during which time, at very short intervals, from my station, about 1,200 yards distance from the copper-roofed tower of the church known as St. Jacobi, about 300 feet high, I saw this phenomenon apparently resting about 30 feet from the summit of the steeple. The colour was a reddish purple, and reminded one somewhat of burning potassium. From repeated comparisons with other objects during the lightning flashes, I judged these fire-balls (two were several times visible) to be from 4 feet to 6 feet in diameter. The longest duration that I timed was 42 seconds. This passing away of such dense masses of electricity by induction was visible some twenty times, but whether performed silently I had no means of ascertaining. From the apparent size of flame and the non-lighting quality of the colour, I estimated it as equal to 10,000 candles. The colour was doubtless the effect of the glare of the copper roof.

DURING 1881 no less than five exhibitions will be held at Frankfort-on-the-Main, viz., a patent exhibition, a horticultural, a balneological, an industrial, and a tanner's and furrier's exhibition.

A MEETING of the members of the Aëronautical Society of Great Britain will be held at the Society of Arts, Adelphi, on Monday, June 21, for the reading and discussion of papers, and generally for the advancement of the Society's interests. The chair will be taken precisely at 8 p.m.

WE are requested to make the following announcement with regard to the Sunday Art Exhibitions of the Sunday Society:—On Sunday, June 20, the first exhibition at the Hanover Gallery, including Hans Makart's great picture of the Entry of Charles V. into Antwerp, will be open to the members of the Society, and on the two following Sundays, June 27 and July 4, the public will be admitted by means of free tickets, which will be issued to those who apply by letter, sending a stamped and addressed envelope to the Honorary Secretary, 6, Dudley Place, W. On each Sunday the Gallery will be opened from 3 till 9 p.m. The Grosvenor Gallery will be opened to the members of the Society on Sunday, July 25, and to the public on Sunday, August 1, by tickets to be had on written application as above.

ON Saturday the Geologists' Association and the West London Scientific Association make a combined excursion to Croydon and Riddlesdown.

THE additions to the Zoological Society's Gardens during the past fortnight include a White-throated Capuchin (*Cebus hypoleucus*) from Central America, presented by Miss Baker; a Toque Monkey (*Macacus pileatus*) from Ceylon, presented by Mr. H. P. Brenan; a Brown Bear (*Ursus arctos*) from Asia, presented by Mr. Chas. Overbeck; a Pig-tailed Monkey (*Macacus nemestrinus*) from Java, presented by Mr. W. C. Lawes; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. T. H. Adey; a Black-eared Marmoset (*Hapale penicillata*) from South-East Brazil, presented by Mr. G. Mantell; three Slender Loris (*Loris gracilis*) from Ceylon, presented by Lord Lilford, F.Z.S.; a Dingo Dog (*Canis dingo*) from Australia, presented by Lord Ernest Gordon; a White Pelican (*Pelecanus onocrotalus*) from North Africa, presented by Mr. J. Simonds; a Musky Lorikeet (*Trichoglossus concinnus*) from Australia, pre-

sented by Mr. A. H. Jamrach; a Horsfield's Tortoise (*Testudo horsfieldi*) from Afghanistan, presented by Capt. Cotton; two Smooth Snakes (*Coronella lævis*), British, presented respectively by Mr. W. Penny and Mr. Thos. J. Mann; two Yellow-headed Troupials (*Xanthocephalus icterocephalus*) from Mexico, presented by Mr. W. A. Conklin; a Jaguar (*Felis onça*) from Bolivia, two Common Boas (*Boa constrictor*) from Savanilla, deposited; a Ring-tailed Lemur (*Lemur catta*) from Madagascar, a Ludio Monkey (*Cercopithecus ludio*), a Mona Monkey (*Cercopithecus mona*), two Rus's Weaver Birds (*Quelea russi*), two Cinereous Waxbills (*Estrelda cærulescens*), two Crimson-eared Waxbills (*Estrelda phœnicotis*) from West Africa, a Black-footed Penguin (*Spheniscus demersus*), a Levaillant's Parrot (*Pœocephalus robustus*), from South Africa, a Brahminy Kite (*Haliastur indus*) from South Asia, a Brown Crane (*Grus canadensis*) from North America, a Double-crested Pigeon (*Lopholæmus antarcticus*) from North Australia, two Swift Parrikeets (*Lathamus discolor*) from Tasmania, two Victoria Crowned Pigeons (*Goura victoriæ*) from the Island of Jobie, four Bengal Weaver Birds (*Ploceus bengalensis*) from India, a Red Lory (*Eos rubra*), an Ornamental Lorikeet (*Trichoglossus ornatus*) from Moluccas, a White-billed Parrakeet (*Tanygnathus albirostris*) from Celebes, a Noble Macaw (*Ara nobilis*) from Brazil, two Yellow-fronted Amazons (*Chrysotis ochrocephala*) from Panama, a White headed Parrot (*Pionus senilis*) from Mexico, two Black-headed Conures (*Conurus nanday*) from Paraguay, two Silky Marmosets (*Midas rosalia*) from South-East Brazil, a Leucoryx Antelope (*Oryx leucoryx*) from North Africa, a Common Otter (*Lutra vulgaris*), British, three Chinchillas (*Chinchilla lanigera*) from Chili, an Upland Goose (*Bernicla magellanica*) from the Falkland Islands, three Ashy-headed Geese (*Bernicla poliocephala*) from South America, purchased; an Anoa (*Anoa depressicornis*) from Celebes, received in exchange; an Axis Deer (*Cervus axis*), a Japanese Deer (*Cervus sika*), a Geoffroy's Dove (*Peristera geoffroii*), a Wonga-wonga Pigeon (*Leucosarcia picata*), a Turquoisine Parrakeet (*Euphema pulchella*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

FAYE'S COMET.—Dr. Axel-Möller commences his ephemeris of Faye's comet for the present year on July 1, when its distance from the earth will be 2·005, and that from the sun 2·53; the perihelion passage will not take place till January 22, 1881. The intensity of light corresponding to the comet's distances on July 1 is 0·039; in 1844 it was observed with sensibly the same intensity, the value for the last observation with the 15-inch refractor at Pulkowa being 0·035. The comet attains its greatest brightness in the middle of October, when the value corresponds to that at the last observation in 1858, with the 9·6-inch refractor at Berlin on October 16. At discovery by M. Faye in 1843 the theoretical intensity of light was 0·54, which has not been approached at any of the subsequent returns. The following positions are taken from Dr. Axel-Möller's ephemeris, which is calculated for Berlin midnight, or about 11h. G.M.T. :—

	Right Ascension. h. m. s.	Declination. ° ′		Right Ascension. h. m. s.	Declination. ° ′
July 1	23 5 25	+7 53·5	July 17	23 13 17	+9 34·5
3	23 6 38	8 7·7	19	23 13 57	9 44·8
5	23 7 47	8 21·4	21	23 14 32	9 54·6
7	23 8 52	8 34·8	23	23 15 2	10 3·6
9	23 9 54	8 47·7	25	23 15 27	10 12·0
11	23 10 51	9 0·1	27	23 15 47	10 19·7
13	23 11 44	9 12·1	29	23 16 2	10 26·6
15	23 12 33	+9 23·6	31	23 16 12	+10 32·8

The comet will arrive at its least distance from the earth (1·09) on October 3. So far as can be foreseen without calculation of the perturbations the comet is not likely to exhibit a degree of brightness approaching that in the year of its discovery by M. Faye, until 1903.

While Faye's comet is followed up by Dr. Axel-Möller in the same admirable manner as for many years past, calculations relating to other comets of short period are in the hands of the following astronomers according to the last Report of the *Astronomische Gesellschaft*:—Dr. Backlund of the Imperial Observatory, Pulkowa, proceeds with the perturbations of Encke's comet, taking up the work where it was left by the late Dr. v. Asten; Brorsen's comet is undertaken by Prof. R. Schulze of Döbeln; D'Arrest's, by M. Leveau of Paris; Winnecke's by Prof. Oppolzer of Vienna; Tempel's comet of 1867 by M. Gautier of Geneva; Tempel's second comet (1871), by M. Schulhof of Paris; and Tuttle's comet, due in the year 1885, by Mr. Ormond Stone of Cincinnati. The exceptional case of Biela's comet is not provided for.

THE GREAT SOUTHERN COMET OF 1880.—Dr. M. W. Meyer, of Geneva, assuming for the period of revolution of this comet the interval between the perihelion passage of the great comet of 1843 and that of the comet in 1880, corresponding to a semi-axis major of 11·0869, has adapted the other elements of the orbit thereto by means of Dr. B. A. Gould's observations at Cordoba on February 6, 12, and 19, covering an interval which, so far as we know at present, is only one day less than the whole extent of accurate observation: the Cordoba observations of February 5 await the meridional observation of the comparison star, which is not found in our catalogues: it may be well determined at one of the observatories of Southern Europe. Dr. Meyer's results are as follows:—

Perihelion passage, 1880, January 27·44242 G.M.T.

	° ′ ″	
Longitude of perihelion ...	278 22 47	Mean equinox, 1880·0
,, ascending node ...	356 16 43	
Inclination of the orbit ...	36 52 13	
Log. excentricity (=log. sine ϕ)	9·9997682	or $\phi = 88° 7' 41''·55$
Log. perihelion distance ...	7·7720095	

Motion retrograde.

The aphelion distance in this orbit is 22·1679 (the earth's mean distance being taken as *unity*), and at aphelion the comet is distant from the orbit of Uranus 13·15. The nearest approach to the orbit of Jupiter, about 3·1, takes place when the true anomaly is about 176° 35′. The comet's orbital velocity at perihelion is 338 miles in a second, and that at aphelion 477 feet in the same interval.

MINIMA OF ALGOL.—The following times of geocentric minima of Algol, observable in this country during the ensuing quarter, are deduced from the elements given by Prof. Schönfeld in his catalogue of 1875. Considerable perturbations of epoch appear to have taken place during the last five years, as we have previously noted in this column, and from the course of the errors of calculation it seems quite possible that the computed times may be nearly a half-hour too late. Systematic observations of this variable are now much to be desired, and it may be hoped that one or more of the many zealous amateur-astronomers here will devote attention to it. The perturbations to which we have alluded were particularly evident in 1876, and the error of the calculated times attained a maximum in the following year, a mean of seven observations by Prof. Julius Schmidt at Athens showing that the computed epoch was too late by forty eight minutes. The following epochs are directly comparable with observation:—

	h. m.			h. m.	
July 16	12 39·0	G.M.T.	Aug. 25	12 47·9	G.M.T.
19	9 27·5	,,	28	9 36·4	,,
Aug. 2	14 19·6	,,	Sept. 14	14 27·7	,,
5	11 8·2	,,	17	11 16·2	,,
22	15 59·4	,,	20	8 4·8	,,

PHYSICAL NOTES

ACCORDING to our contemporary *l'Électricité*, M. Exner of Vienna has discovered that a bismuth-antimony pair immersed in a gas incapable of acting chemically on either of these metals yields no current when one junction is heated. Also that if two bars of copper are soldered together to form a "pair" no current is produced when either junction is heated in air (as would be expected in a circuit of one metal), not even when both strips are exposed to the action of chlorine; but that if one strip only is exposed to chlorine gas and then one junction be warmed a thermo-electric current is set up. According to Exner therefore, all so-called thermo-electric currents are due to chemical action. It would be easy for some of our ardent young physicists to put to the test this very remarkable announcement, and see whether

it is Herr Exner, or all the authorities on thermo-electricity from Seebeck to Tait, on whom we are to rely for the facts.

In a new capillary electrometer described by M. Debrun in the *Journal de Physique* (May), the microscope is dispensed with, and the requisite sensibility obtained by inclining the tube, which is slightly conical. The capillary tube is bent into a somewhat zig-zag shape, the two turned-up ends opening into larger tubes, and with the mercury in these wires are connected. The support can be turned in a vertical plane, so as to give the middle part of the capillary tube any desired inclination.

M. Crova commends, for photometric purposes (*Journal de Physique*, May), M. Prazmowski's polariser, which is a Nicol, with faces normal to the axis of the prism, the two halves of which are joined with linseed oil. It requires large pieces of spar, and the joining is long and difficult, but there are several advantages. Thus the layer of oil (unlike Canada balsam), causes hardly any loss of light; its index, 1·485, being nearly equal to the extraordinary index of spar, the polarised field is limited on one side, as in Nicols, where the total reflection of the ordinary ray commences, by a red band; but these cond limit, corresponding to total reflection of the extraordinary ray, is thrown out of the field of vision; the angular value of the polarised field is thus increased. The increase of field, the angular separation of the only coloured band, and the direction of its bases, normal to the axis, are qualities to be appreciated in certain cases.

According to some recent experiments of M. Goulier, the coefficient of expansion by heat of a metal is independent of any pressure put upon the metal, and is the same under a stress of traction as under one of compression.

Mr. W. P. Johnson gives an account in the *Philosophical Magazine* of a new use of the telephone. It is sometimes necessary to grapple and lift a faulty cable, and if it lies in the water along with other cables of similar exterior make it has hitherto been impossible to decide, without cutting it apart, on the identity of the grappled portion. To avoid the obvious evil of having to cut and splice the cable unnecessarily, it is now suggested to employ the telephone on an auxiliary parallel wire in which the induction may be sufficiently strong to enable the electricians in charge to read the signals which may be sent into the cable, and so identify it.

The following pretty experiment, devised by Mr. R. H. Ridout, illustrates the surface tension of mercury. A shallow tray, six inches by three, is supported on three levelling screws, and inclined just so that the mercury does not flow over the lipped edge. If now a small quantity of the liquid be set flowing over the edge it will draw the rest of the liquid over with a siphon-like action. It is difficult, however, to get the surface so clean that no adherent trail should be left, marring the completion of the experiment.

The expansion of glass by heat may be demonstrated as follows:—A glass tube of narrow bore and about eighteen inches long is bent round in the shape of a horse-shoe, so that the free ends are within a millimetre of one another. Between these ends a coin may be held, being nipped between the ends of the rod and held there by the grasp due to the elasticity of the glass. If now the *outer* portion of the curved part be warmed, the ends open slightly and the coin drops out. This experiment is also due to the ingenuity of Mr. Ridout.

The phenomenon lately discovered by Hall of the action of a magnet in altering the path of a current of electricity in the conductor which carries it, has formed the starting-point for two investigations, which have appeared separately in the *Wiener Anzeiger*, by Boltzmann and von Ettingshausen respectively, in which they point out that this discovery may be applied to determine the absolute velocity of electricity in a conductor.

M. Louguinin has published in the last fascicule of the *Journal* of the Russian Physical and Chemical Society (vol. xii., fasc. 4) a note on his important work on the heat which results from the burning of several alcohols. The substances experimented on are burnt in a jet of oxygen in a glass vessel which is placed in the water of a calorimeter. The figures are: For normal propylic alcohol, 481·6 calories for one molecule; isopropylic alcohol, 479 calories; isobutylic alcohol, 638·6 calories.

GEOGRAPHICAL NOTES

Mr. Carl Bock has lately returned to London after his journeys in Borneo, bringing with him a magnificent series of portraits of the native tribes of that island,—both Dyaks and forest people—taken in water colours. These, we understand, are to be reproduced, at the expense of the Dutch Government, by chromolithography, and will illustrate his report on the journey, which is to be read in the first instance before the Royal Geographical and Anthropological Society of Holland. Pending the publication of this report, Mr. Bock refrains, at the desire of the Dutch Government, from anticipating it in England even by a preliminary sketch. The varieties of type, the methods of adornment, the manner, and to some extent the religion of these distinct races, are all brought out in Mr. Bock's faithful drawings taken from the life on the spot, which form, over and above the objects for which the journey was taken, a splendid contribution to ethnography, the publication of which will be looked forward to with interest; the greater perhaps if Mr. Bock were permitted to give some further slight outline than has already appeared in the pages of Nature. Mr. Bock has also made an extensive collection of the swords, lances, blowing tubes, and shields (some of the latter covered with human hair), which are used by the natives. He seems to have had the happy knack of making friends of the savages whom others have found murderers, and has brought himself back alive to receive the honour that is his due.

The current number of the Geographical Society's *Proceedings* opens with the Rev. C. Maples' very interesting paper on Masasi and the Rovuma district between Lake Nyassa and the east coast of Africa. The Rev. C. T. Wilson's and Mr. Felkin's brief notes on Uganda and the journey through the Nile region are also published, and are followed by an account of that rare occurrence in Dominica, a volcanic eruption at the Grand Souffrière, which took place on January 4. The geographical notes include a list of latitudes in Central South Africa, Mr. F. C. Selous' explorations on the Zambesi, &c. (of which full accounts are to be published in a later number), and a journey in Damara-land and beyond the River Okavango. An allusion is also made to Mr. Whymper's ascent of Cotopaxi, and to a proposed exploration of some of the unknown affluents of the Purûs. Among the remaining notes is a long account of the country of the Mijjertain Somalis, and of recent exploration in Central Australia. Col. H. Yule furnishes an obituary notice of General Macleod, whose pioneer journey into the interior of the Indo-Chinese Peninsula in 1836-7 is, we fear, now almost forgotten. The map this month is that of the central portion of South Africa, illustrating Dr. Emil Holub's journeys, and constructed in part from his original drawings.

Dr. Emil Bessels, who was with Hall in the *Polaris*, hopes to undertake a new Arctic expedition in 1881 on funds subscribed in America. He will establish a station at the entrance of Jones Sound, where a scientific staff will be located, consisting of an astronomer, a physicist, a geologist, botanist, and zoologist. Intercourse will be kept up with the settlement of North Greenland by means of a yacht, as well as with the whalers.

Signor Cristoforo Negri, President of the Italian Geographical Society, and member of the Geographical Society of London, has just published an interesting pamphlet at Genoa, in which he warmly advocates the proposed Italian Antarctic expedition. He demonstrates the importance not only to science, but probably also to trade, of such an expedition. A special circumstance increases the desirability of this Italian Antarctic expedition. In 1882 the transit of Venus will again occur, but after that not again for a hundred years. The Italian expedition, therefore, finding itself in 1882 at some point of the Antarctic circle, would be able to observe this phenomenon under favourable conditions. Signor Negri believes that the expedition might be made with a single vessel at no very extravagant cost, perhaps 600,000 to 700,000 Italian lire. It would spend two winters, returning to La Plata, if necessary, during that period, to re-provision and re-coal the ship.

At the last meeting of the Russian Geographical Society the Secretary intimated that M. Potanin continues his exploration of North-Western Mongolia. The Society has just received from him a part of his collections, and expects soon to receive his detailed report. M. Tiaghin, who stays on Novaya Zemlya for the exploration of that island, has brought together a very good collection of plants, and has made interesting communications as to the geography of the island. As to new expeditions, the Society proposes to send M. Mereshkovsky to the Crimea for ethnographical and archæological explorations, and M. Malakhoff to the Middle Ural Mountains for zoo-geographical investiga-

tions. M. Maikoff presented a report of the Committee appointed to discuss the subject of a thorough historical and ethnographical exploration of Bulgaria. Col. Lebedeff presented a sketch of the orography of the Balkan peninsula, according to the last geodetical and topographical operations in Bulgaria by officers of the Russian General Staff. The orography of much of the Balkan peninsula has been pretty well studied, a complete trigonometrical report having been completed, and a relief-map on a large scale, like that of the Caucasus, is now in preparation.

A LIVELY controversy having arisen between the cantons of Geneva and Vaud as to the importance of the dam erected at Geneva with reference to the level of Lake Leman, the *Journal de Genève* has published during the past month a series of papers by M. H. de Saussure on Lake Leman, the changes of its level, the destructive action of its waves, and generally on its physical conditions. These papers have a great scientific value. We notice also several papers on the same subject published by the *Gazette de Lausanne* in answer to M. de Saussure's articles.

WE notice an interesting note by MM. Polonsky and Meyer on that part of the eastern shore of the Caspian which is described as Tentiak-sor, and is a former lake now transformed into a series of lagoons separated by muddy spaces. Its origin is explained by M. Meyer by a falling of level of the Caspian. Prof. Lenz having made an incision in a rock at Baku in 1830, the subsequent measurements showed that the level stood—in 1837, 1·6 feet lower; in 1847, 0·7 feet higher; in 1848, 1·3 foot; in 1852, 2·9 feet; in 1853, 2·5 feet; and in 1861, 3·9 feet lower than in 1837. This circumstance would be in complete accord with the general diminution of water in all Asiatic lakes, and would perfectly explain a multitude of important physico-geographical phenomena.

HEFT V. of *Petermann's Mittheilungen* begins with an article by C. Marten, on the Inhabited Part of Chili South of the River Valdivia; Dr. Behm gives some collected information on the gold-fields of Wassa, on the Upper Ankobra, north from the Gold Coast; Dr. Junker narrates his journey through the Libyan Desert to the Natron Lakes; and Herr Bernhard von Struve writes on the history of trade-routes in East Siberia. The Ergänzungheft No. 61 consists of a physico-geographical account of the Portuguese Mountain group, the Serra da Estrella, with special reference to its forestal conditions, by Herr J. Rivoli. In the June number Dr. A. Regel gives an interesting account of a visit he made last year to Turfan, in Central Asia. Dr. Emin-Bey describes his journey from Dufilé to Fatiko in December, 1878, and January, 1879. Herr Lindemann gives some statistical information on the forests of Bavaria in connection with a map of the Bavarian Spessart. Herr E. R. Flegel gives a detailed narrative of his journey in the *Henry Venn* in July and August last year, up the Binué, from Gandé to Djen.

THE *Japan Mail* states that development in the trade between Japan and Corea is confidently anticipated in consequence of the opening of the port of Gensan. The Japanese residents at Fusan, in the south of the Corean peninsula, are said already to exceed 14,000 in number, and we may therefore hope that we shall soon have more detailed information regarding the interior of the country than has hitherto been accessible.

THE Melbourne correspondent of the *Colonies and India* states that Mr. White, of the Reed Beds, near Adelaide, has fitted out the schooner *Elsea*, and has left on an exploring cruise to New Guinea for the purpose of making natural history investigations, which are expected to occupy two years.

IN the introduction to his lately published report on the trade and commerce of the Caucasian Provinces, Mr. Lyall, H.B.M.'s Consul for Tiflis and Poti, gives a succinct account of the geographical features of this region, accompanied by remarks on its climate, resources, communications, &c. Though the information is not perhaps entirely new, it is interesting to be able to take in at a glance so much relating to a tract of country which is daily becoming more and more important.

COL. FLATTERS, who had left Wargla on March 15 with a column of 100 men for an exploration in connection with the intended Trans-Algerian Railway, returned to Wargla on May 20, after having travelled 600 miles in the direction of Raof, without meeting any opposition from the natives. He intends to resume his explorations in the months of September or October, in another direction. He was unable to discover the Ighorghor Wed, which is marked on every map.

FROM August 5 to 10 next the French Geographical Society will meet at Nancy for their triennial meeting.

WE have received Parts 12 to 16, each containing three maps, of the new edition of Stieler's "Hand-Atlas."

THE Russian Department of Estates has just published an interesting atlas of six maps, representing the distribution of soils in Russia. The atlas is accompanied by a text by M. Dokoutchaeff. The maps were drawn five years ago by M. Tchaslavsky, who has studied this subject during many years.

THE ROYAL OBSERVATORY

THE following are the points that seem to us of most interest in the Report of the Astronomer-Royal to the Board of Visitors at their recent Visitation:—

The Admiralty have decided not to proceed with the erection of a new library at present, though the space has been cleared, admitting of the erection of a building fifty by twenty feet. The Astronomer-Royal proposes to erect here a room of one story, but with galleries at mid-height, so that there would never be need to use a ladder. Among other changes occurring in this clearance, he has removed the electrometer mast (a source of some expense and some danger); the perfect success of Sir William Thomson's electrometer rendering all further apparatus for the same purpose unnecessary. With regard to the library the Report states that no change has been made in plan, but in some departments the number of books has increased rapidly. "Fundamental astronomy advances slowly, magnetism is almost stationary, geodesy progresses, photography and spectroscopy increase very fast, and meteorology the most rapidly of all. The Transactions of foreign Academies increase in number. This is owing, I imagine, to the general scientific activity, both of Academicians and of private men of science, in most foreign countries, and to the facilities given for transmission, by the courtesy of publishers and by the extension of book post."

Under the head of Astronomical Observations, the Report says: "The sun, moon, planets, and fundamental stars are the regular subjects of observation on the meridian, special attention being devoted to the moon, which is also observed at every available opportunity with the altazimuth. Other stars are observed from a working catalogue of about 2,500 stars, with which good progress has been made in the past year, though a large number of stars still remain for observation. About 1,100 stars were observed in 1879." Between May 20, 1879, and May 9, 1880, the following observations were made:—With the transit circle 4,164 transits, the separate limbs being connected as separate observations; 3,953 circle-observations; with the reflex-zenith tube, 23 pairs of observation of γ Draconis; with the altazimuth, 713 azimuths of the moon and stars and 352 zenith distances of the moon. A set of micrometer-measures of the outer satellite of Mars and several sets of measures of the satellites of Saturn, were obtained last autumn with the south-east equatorial, and a few drawings of Mars and Jupiter were made near the time of opposition. A remarkable proof of the exceptionally bad weather of last summer is found in the fact that in July it caused the loss of a whole month's observations of the sun.

Under the heading of Spectroscopic and Photographic Observations we find the following statement:—"The sun's chromosphere has been examined on thirty-seven days during the period to which this Report refers, and on thirty-four days prominences were seen. Whenever practicable, the appearance of the prominences as seen on each of the chromospheric lines has been recorded, and on four days a detailed examination of the whole spectrum of the chromosphere was made at twenty-four points of the sun's limb. Three sun-spots have been examined with reference to the broadening of lines in their spectra, and fifteen photographs have been taken of the spectra of three sun spots. As regards the spectroscopic determination of star-motions, 113 measures have been made of the displacement of the F line in the spectra of 29 stars, 44 of the b_1 line in 19 stars, and 6 of the b_4 line in 3 stars. Of these 51 stars 21 had not previously been examined. In the case of three of the stars a dispersive power equivalent to that given by fifteen prisms of 60° was used. The stars are taken from a working list of 150 stars, which may eventually be extended to include all stars down to the fourth magnitude, and it is expected that in course of time the motions of about 300 stars may be spectroscopically determined. The spectra of comets *c* (Swift's) and *d* (Palisa's)

1879, and of the red spot on Jupiter, have been examined, but no certain results were obtained. Between 1879, May 20, and 1880, May 9, photographs of the sun were taken on 145 days, and of these 270 have been selected for preservation. The photographs show a complete absence of spots on 64 days out of 145, whilst in the preceding year there was a similar absence of spots on 121 days out of 150. The epoch of minimum appears to have occurred about the beginning of 1879, and since last October the outbreak of spots has been very marked." Various spectroscopic and photographic results, it is stated, have been communicated to the Committee on Solar Physics, with whom, the Report states, the Observatory is in friendly communication.

Under Magnetical and Meteorological Instruments we are told that the Thomson electrometer is in excellent order. "In the warm weather of summer, and in winter when much artificial heat is used in the basement, the photographs have been unsatisfactory, but we are endeavouring to remedy this by cutting off all communication with air from the basement. In the winter the register was frequently interrupted by the freezing of the water in the exit-pipe. A basin (with cesspool) has been recently constructed to carry off the water discharged from this pipe. The action of the photographic barometer appears to have been improved by the slight changes mentioned in the last Report, and small movements are in many cases excellently shown. A new pressure-plate with springs has been applied by Mr. Browning to Osler's anemometer, and it is proposed to make such modification as will give a scale extending to 50 lbs. pressure on the square foot. Other parts of the instrument have also been renewed. An arrangement for slow motion of the barrel, which was much wanted in adjusting the recording paper, has been fitted to Robinson's anemometer. It is in contemplation to alter the photographic cylinders of the magnetometers, barometer, thermometers, and earth-currents apparatus, so as to make the time-scales of all the magnetical and meteorological instruments the same."

Some interesting information is given under the head of Reduction of Magnetical and Meteorological Observations.

The following are given as the principal results for magnetic elements in the year 1879:—

Approximate mean westerly declination	18° 40′
Mean horizontal force	3·911 (in English units). 1·803 (in Metric units).
Mean dip	67° 36′ 5″ (by 9-inch needles). 67 36 54 (by 6-inch needles). 67 37 47 (by 3-inch needles).

"On the application of the Committee on Solar Physics, the separate daily values of the diurnal range of magnetic declination for the years 1848 to 1858 have been supplied to Prof. Balfour Stewart."

The Report goes on to say:—"The Visitors at their last meeting suggested the advantage of preparing a digested account of the magnetical results obtained at the Royal Observatory from 1841 to 1876, similar in some respects to the account of meteorological results recently published. A beginning was made by preparing the monthly means of diurnal inequality in force and direction through the whole period, and exhibiting their combination in curves. It is known to the Visitors that, in two communications to the Royal Society, I have exhibited numerically and in curves the means of these monthly results (yearly means through all months, and monthly means through all years) as far as the year 1863. In 1864 observations were interrupted by the work in progress for the magnetic basement, so that the reductions now to be made commence with 1865. The monthly results through the whole period being taken as before, the next step, for obtaining exhibitions which the eye and the mind could easily command, was to collect the monthly conclusions into a limited number of groups of years. On inspecting the monthly curves in detail there was no hesitation in fixing upon the following:—First group, 1865 to 1868; second group, 1869 to 1872; third group, 1873 to 1876. In each of these, as before, yearly means are taken through all months, and monthly means through all years. The curves in the second group are strikingly larger than those in the first and third; the linear dimensions of the curves of 1870 are fully $\frac{5}{3}$ of those of 1876 in the east-and-west direction, and fully $\frac{4}{3}$ in the north-and-south direction. In the study of the forms of the individual curves; their relations to the hour, the month, the year; their connection with solar or meteorological facts; the conjectural physico-mechanical causes by which they are produced; there is much to occupy the mind. I regret that, though in contemplation of these curves I have remarked some singular (but imperfect) laws, I have not been able to pursue them. The heavy load on the Observatory, and the limited means (in the present year) of supporting it, will in part explain this."

Under "Chronometers, Time-signals," &c., we are told that during the period to which the Report refers the error of the Westminster Clock exceeded 1s. on 120 days; on 32 of these it was between 2s. and 3s., on 4 days between 3s. and 4s., and on 1 day it exceeded 4s.

"I have reason to believe," the Astronomer-Royal states, "that the use of the time-signals, originating at the Royal Observatory, and distributed automatically from the General Post Office, is becoming more and more extensive, and it seems probable that the same system may be adopted by foreign nations. Very lately an examination of our instruments was made on the part of another country, with the view of establishing something similar in one of their maritime cities; and it was intimated that Greenwich time would probably be used as standard. The establishment of time-balls, &c., at foreign ports is increasing."

With regard to the progress of the operations in connection with the transit of Venus, 1874, it is stated that permission was given by the Treasury to Major Tupman last September to devote his time to the work till the end of June, 1880. The result is (taking the stations or station-groups in the order which the Astronomer-Royal proposes for publication): the observations and calculations of the Sandwich or Hawaiian group are completed; those of the Egyptian group nearly finished; those of Rodriguez completed; those of Kerguelen nearly finished; and also those (which unfortunately are less important) of New Zealand. "In January of the present year I received through the Admiralty the notification of the Treasury that the printing of the observations and calculations might proceed. It has gone on rather languidly; but I have before me in type 128 pages, including the text and the greater portion of the tabular part of the Honolulu work. I propose to take steps for urging on this printing."

"With regard to the transit of 1882," the Report goes on to state, "I have lately placed a memorandum before the Royal Astronomical Society. From the facility with which the requirements for geographical position are satisfied, and from the rapid and accurate communication of time now given by electric telegraph, the observation of this transit will be comparatively easy and inexpensive. I have attached greater importance than I did formerly to the elevation of the sun. For the four principal phases (ingress accelerated, and retarded; egress accelerated, and retarded) I propose to rely mainly on: 1st, the Cape Colony; 2nd, the shores of Canada and the United States, Bermuda, and the West India Islands; 3rd, the same as the 2nd; 4th, the eastern shore of Australia, or New Zealand in preference if telegraph communication be made. I remark that it is highly desirable that steps be taken now for determining by telegraph the longitude of some point of Australia."

The Astronomer-Royal makes the following statement in reference to his own lunar theory:—"The general principle of this is: to adopt for correction the best existing theory; to compute with the severest accuracy the numerical values of the terms produced geometrically by the tabular coefficients, and also the terms really due to the forces which produce them; and to remove the differences between these by corrections of the tabular coefficients, for which corrections proper factors are prepared. It was a special object with me to avoid the use of powers of *m* (a symbol well known to lunar theorists), and to give easy means of computing, not new absolute values, but corrections of existing numerical coefficients (a principle which I have adopted extensively in other branches of astronomy), and also of computing the effect of small external disturbances or small changes of force. Both these are obtained by my process. The heaviest part of the work is the severe computation to which I have alluded, and this is done entirely by junior computers. The calculations had been carried out in every part to the accuracy of 10^{-7}; but for securing the degree of accuracy which I proposed it was found necessary to extend many parts to 10^{-8}, and some to 10^{-9}. This has caused a very great addition to the labour, but the work has advanced well, and will, I trust, be finished ere long. While waiting for this, which is to give the correction to every coefficient of the ordinary lunar theory, I am employing myself partly in rearranging the whole work for

publication, and in putting calculations in order for that correction of coefficients; and partly on three ramifications or supplements of the theory relating to the effect of the earth's oblateness, the effect of change of position of the ecliptic plane, and the effect of change of excentricity of the earth's orbit, and lunar acceleration. The last of these I have completed to my satisfaction, requiring only an examination of the external factor; the two others are progressing. The Admiralty have assisted me, on estimates, with a moderate grant (of amount named by myself), but much of the expense has been private."

The Report concludes as follows:—"After the details into which I have entered as applying to the present state of the Observatory, and after the remarks which I have made in the two reports last preceding on the question of reduction of printing (which at some fitting time I would willingly again present to the consideration of the Visitors), and the note in the last report on the increase of annual expense, I have only to place before the Visitors, but for no immediate expression of opinion, the impression which frequently weighs upon me as to the ulterior organisation of the Observatory. The determination of places of stars, sun, moon, and planets, was handed down to me from my predecessors; it has in various ways been much extended. The magnetic and meteorological observations (the first originating with myself, the second partly with the movement introduced by the Royal Society and partly by myself) constituted a distinct branch of science, having this property in common with the original astronomical work, that it is incessant and regular. The much later introduction of photographic and spectroscopic astronomy, established at the instance of the Board of Visitors, and carried on with vigour and regularity, has created a third department. All these departments appear at present to be working efficiently and well. But I can easily imagine circumstances which would interfere materially with the successful continuation in one place of this triplicate series of observations. Though I think this possibility of partial failure worthy the contemplation of the Visitors, yet I do not see any necessity for action of any kind at the present time."

INTERCOLONIAL METEOROLOGICAL CONFERENCE AT SYDNEY

A METEOROLOGICAL Conference was held at Sydney in November last, the representatives of the different Colonies being Messrs. James Hector for New Zealand, Charles Todd for South Australia, R. L. J. Ellery for Victoria, and H. C. Russell for New South Wales, the last-named gentleman being chairman. The most cordial unanimity characterised the meeting, which lasted from the 11th to the 14th of the month, and the resolutions arrived at with a view to secure united action in their meteorological investigations and uniformity in the methods and times of observing and forms of publication augur well for the future of meteorology in the Australian Colonies. The whole question of weather telegrams was under anxious consideration. The system in present operation embraces only the Colonies of South Australia, Victoria, New South Wales, and Queensland, but a resolution was passed declaring it desirable to secure the co-operation of the Governments of Western Australia, Tasmania, and New Zealand in the system of inter-colonial weather telegrams. The facts pointed out by Mr. Todd as to the great regularity observed by the atmospheric disturbances in pursuing a course from west to east, and the statement by Dr. Hector that early notices could be sent from Queensland of the origin and progress of the dangerous and suddenly occurring cyclones that cross the northern part of New Zealand, sufficiently attest the practicability of the system of weather warnings and their practical value. For instance, the great storm which wrecked the *Dandenong* in September, 1876, could have been telegraphed in sufficient time to have prevented the great loss of property which took place at the different ports along the coast of New South Wales. We have the greatest pleasure in noting a deliverance by the Conference to the effect that weather telegrams and forecasts shall in all cases depend upon the observations used for general meteorological and climatological statistics. Much emphasis was laid on the establishment of high-level stations with a more special view to the investigation of the winds; and the Conference recommended that there be established in each of the Colonies, upon a high mountain peak, a meteorological observatory for the special study of winds and other meteorological phenomena, the most desirable positions being Mount Lofty, in South Australia, 2,500 feet high; Kiandra, in New South Wales, 4,600 feet; Mount Wellington, in Tasmania, 4,000 feet; Mount Macedon, in Victoria, 3,500 feet; and in New Zealand, Tauhara Taupo, 4,600 feet, and Mount Herbert, 4,000 feet. We hope that the Governments of the different Colonies will vote the small sums which are required to carry out the resolutions of the Conference, the giving practical effect to which will certainly confer substantial advantages on commercial, shipping, and other interests, and contribute materially to a more satisfactory development of the meteorology of this important part of the globe.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—At St. John's College Prof. Liveing has been elected to a foundation fellowship, and Dr. Kennedy, Prof. Sylvester, F.R.S., and Prof. Churchill Babington were elected honorary fellows of the society.

The following awards for proficiency in natural science have been made at St. John's College:—A Foundation Scholarship to Samways; a Proper Sizarship to Love, and Exhibitions to Hart (already scholar), Weldon, Edmunds, Love, T. Roberts. Fleming was awarded one of the Hughes Prizes, given to the two most distinguished third-year students in any branch of study, and a Wright's Prize, with augmentation of the year's emoluments to 100*l.* The Open Exhibition was awarded at Easter to Scott-Taylor (City Middle-class School, Cowper Street), and a second Exhibition to Clementson (Newcastle-under-Lyme).

We understand that Mr. W. J. Lewis has been appointed to perform the duties of Professor of Mineralogy at Cambridge until the close of the year, the period to which the election to the chair has been postponed by the University Commissioners.

SCIENTIFIC SERIALS

Zeitschrift für wissenschaftliche Zoologie, May.—Prof. Zygmunt Kahane, on the anatomy of *Tænia perfoliata*, Göze, as a contribution to the knowledge of the Cestoids, with a plate and a woodcut. The actual facts recorded in the paper were originally laid before the Academy of Sciences of Krakau in May, 1878, and were afterwards published in a somewhat altered form, in the Polish tongue, in their *Proceedings*. The investigations were carried on during the summer and autumn of 1877 in the Zoological Institute at Leipzig, under the supervision of Prof. Leuckart. The history of the species is treated at length, and the paper extends over seventy-seven pages.—Dr. G. Haller, Contribution to a knowledge of the Tyroglyphidæ and their allies, with three plates: describes a new species of Listrophorus (*L. pagenstecheri*): On the genus Homopus, Koch. It is not an independent genus, but the forms are only the larval stages of Dermacarus, which is described as a new parasitic genus; *Tyroglyphus megninii* is described as a new species. There is a sketch of a delineation of the internal anatomy of Tyroglyphus and Dermacarus, and of the egg in these genera.—Prof. Ludwig Stieda, on the structure and development of the *Bursa fabricii*, with five woodcuts.—Dr. Hubert Ludwig, on the primary sand canal in the Crinoids, with some remarks on the comparative anatomy of the Echinoderms in general, with two plates.—Dr. H. Ludwig, new contributions to the anatomy of the Ophiuroids, with three plates.

Journal de Physique, May.—Measurement of the electromotive forces of batteries and electromotive forces of contact of metals, by M. Pellat.—Study of polariser-prisms used in photometric observations, by M. Crova.—On the illumination of electrodes, by M. Colley.—On a new capillary electrometer, by M. Debrun.—To determine with the aid of an articulated system the conjugate points of an optical system, by M. Elie.

Archives des Sciences Physiques et Naturelles, May 15.—On the earths of samarskite, by M. Marignac.—Researches on the condensation of gases on the surface of glass, by M. Chappuis.—The Siemens machine and its application to transmission of force, by M. Achard.—Specific heat, latent heat of fusion, and point of fusion of various refractory metals, by M. Violle.

THE *Reale Istituto Lombardo di Scienze e Lettere, Rendiconti*, vol. xiii., fasc. iv. and v.—The phylloxera considered in rural economy, by S. Cantoni.—Geological notes on the basin of Lake d'Orta, by Dr. Parona.—Health and beneficence; their mutual relations, by Dr. Zucchi.

Fasc. vi. and vii.—On the convenience of forming national nurseries of vines resistant to phylloxera, by S. Trevison.—On the chronological determination of Luganese porphyries, by Prof. Taranelli.—On the fundamental equation in the theory of linear differential equations, by Prof. Casorati.—Representation on punctuated space of some forms of the third species composed of straight lines, by S. Archieri.—On the institution of two new genera of arachnida, by Prof. Pavesi.—Electricity and earthquakes, by S. Serpieri.—List of algæ of the province of Pavia, by Dr. Cattaneo.—Second case of peritoneal tranfusion with good success in an oligocitæmic insane person, by Profs. Colgi and Raggi.—On a transformation of the fundamental equations of hydrodynamics, by Prof. Faci.

THE *Revue Internationale des Sciences biologiques*, May, contains:—E. A. Schaefer, on the development of animals.—Carl Hoberland, infanticide among the ancients and the moderns.—L. Pasteur, on the cholera morbus in fowls; on virulent maladies and on vaccination.—M. Debierre, man before and on the threshhold of history, a study of palæontological facts and of comparative archæology and philology.—Notice of learned societies.—The Academy of Sciences, Paris.—The Academy of Sciences, Amsterdam.—The Anthropological Society of Paris.

Morphologisches Jahrbuch, vol. vi., part 2.—Dr. A. Rauber continues his articles on the evolution of form and its transformations in the development of vertebrata, reaching its second section, on the multiplication of axes, pp. 56, with four plates and seven woodcuts illustrating various early stages of monstrous double-axial structures in various species of Salmo and Gallus.—Dr. J. Brock occupies 112 pages, illustrated by two plates, in endeavouring to establish a satisfactory phylogeny of the dibranchiate cephalopods.—Dr. H. von Thering contributes, on the vertebral column of *Pipa*, to the homology of its individual vertebræ and nerves with those of other anura.—Smaller contributions by Prof. Gegenbaur and by C. Rabl (on Planorbis development).—Reviews of German text-books of anatomy.

Gazetta Chimica Italiana, Fasc. iii. and iv.—On the ulmic matter obtained from sugar by action of acids, by S. Sestini.—On some derivatives of β-chlorobutyric acid, by S. Balbiano.—The diffusion and physiological state of copper in the animal organism, first announced by Bartolomeo Bizio, and elucidated by Prof. Giovanni Bizio.—Notice on the chemical constituents of *Stereocaulon vesuvianum*, by S. Paterno.

Bulletin of the United States Geological and Geographical Survey of the Territories, vol. v. No. 3, November 30, 1879.—J. A. Allen, on the species of the genus Bassaris.—W. H. Patton, the American Bembecidæ tribe Stizini; list of a collection of Aculeate Hymenoptera from North-Western Kansas; Generic arrangement of the bees allied to Melissodes and Anthophora.—George B. Sennett, further notes on the ornithology of the Lower Rio Grande of Texas, made during 1878, with annotations by Dr. E. Coues.—Henry Gannett, additional lists of elevations. Among these is a list of the mountain-peaks forming the Cordilleras of North America and of their passes.—Dr. Morris Gibbs, annotated list of the birds of Michigan.—Dr. Le Conte, the coleoptera of the Alpine Rocky Mountain Regions, Part 2.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 27.—"On the Structure and Development of the Skull in the Batrachia. Part III.," by W. K. Parker, F.R.S. (Abstract.)

Some of the work brought forward in this paper was in hand before the first part was in print. That initial piece of work dealt only with the formation of the skull in the common frog, but it was followed by another which appeared in the *Philosophical Transactions* in 1876, which treated of the skulls of the *common* and of the "aglossal" toads.

Of the latter types only two kinds are known, viz., the nailed toad of the Cape (*Dactylethra*), and the monstrous toad of Surinam (*Pipa*). All the bulk of the Batrachia are included in the sub-group "Opisthoglossa." These have a tongue, and in most cases it is free *behind* and not in front; the "Proteroglossal" Batrachia are very few in number, and the character itself (as Dr. Günther informs me) is not well pronounced.

I have now worked out the skull, in one or more stages, in about a *tithe* of the known species, and in my second paper in both of the aberrant ("aglossal") types; in them this was done in various stages.

I am not aware that there is any "order" of any "class" in the Vertebrata where so large a percentage of species has been, or indeed *need be*, worked out, either in the skull or in any other part of their organisation.

That which calls for it here is the great and unlooked-for polymorphism of the species; I may explain this by saying that the skull, in really important modifications, differs more in the species of some of the genera than it does in the orders of some of the classes. As an instance, it would be no easy thing to find a malacopterous fish differing from an acanthopterous type, in deep-seated essential matters, so much as the common toad does from the other native species, viz., the *Natterjack*; and the common frog has only about half as many cranial elements as the bull-frog of North America.

If the metamorphosis of a single species be worked out exhaustively, it gives a range of structural characters which rises up from a larval creature on the level of the lampreys to a reptilian form not far below the Chelonia, and evidently related (obliquely, not genetically) to that "order."

Moreover, whilst the "opisthoglossa" have larvæ with suctorial mouths, and a *quasi-petromyzine* structure altogether, the larvæ of the "aglossa" need only to be arrested as larvæ and to acquire a dense bony armature to be very close counterparts of the most *bizarre* forms of the ganoids of the "old red sandstone," such as *Pterichthys* and *Coccosteus*.

The Batrachia show some remarkable things in their metamorphosis, both as to the *size* their larvæ obtain and the *time* during which metamorphosis is taking place.

In the bull-frog (*Rana pipiens*) the larvæ attain the length of about 5 inches, and take two or three years for their transformation; they may be hindered in this, and be made to take twice that time. In these the larvæ bear a moderate relation, as to size, to the adult form, which may be 7 inches long, although tailless.

But in a frog from the neotropical region (*Pseudis*) scarcely larger than our native form, the tadpole attains the length of nearly a foot, the tail acquiring a breadth of 4 inches.

As zoologists well know, it is easy to procure *tadpoles* of this species, but very hard to get an adult. I am of opinion that the adult condition is not attained until after many years; and it suggests itself to me that this species may be the not remote descendant of a type which did not finish its *anural* metamorphosis.

On the other hand, some of the neotropical forms have very small tadpoles. *Bufo chilensis*, a large toad, has them about half the size of those of our common native Batrachia, and the newly-metamorphosed individuals are no larger than a house-fly.

But in *Pipa* the small larvæ are thoroughly metamorphosed in the maternal dorsal pouches, and at first only do they show a trace (and only a trace) of branchial tufts.

These tadpoles, which never see the light as such, have wide mouths (not suctorial), and so also have the tadpoles of the other waif of the sub-order "Aglossa," viz., *Dactylethra*. In that kind, however, the larvæ become large, and are a long while undergoing their transformations, which take place in the water, according to rule.

In the skull of the adults much variation is evidently due to the different *size* to which the species attains; some, as the bull-frog, are as large as the common Greek tortoise; others grow scarcely larger than a bluebottle fly. As a rule these small kinds show two kinds of modification: they are apt to retain certain larval characters, and they are apt to acquire generalised characters such as do not normally appear in this group, which is very remarkable for the *fewness* of the parts or elements composing the adult skull.

Some of the large forms, as *Rana pipiens*, have many investing bones in their skull, such as must be looked for again in archaic and extinct types, whilst others, as *Ceratophrys* and *Calyptocephalus*, have a cranial armature that is dense, extended, and almost "ganoid;" this kind of skull, however, is found in middle-sized types also, as in *Pelobates* and *Nototrema*.

In the terminal suctorial mouth of the larva of the Opisthoglossa the mandibular pier and its free "ramus" are carried to the front of the head. After transformation, in the larger kinds, the gape is carried behind the head, as in the crocodile; it can be guessed how much modification such a change as this will necessitate.

But it is evident that a low suctorial fish, such as the *tadpole*

is, must have altogether a totally different kind of skull and skeleton to that of an active, noisy, intelligent, more or less terrestrial reptile, such as the frog becomes.

This necessarily great change involves some very curious and instructive *anachronisms*, so to speak, in the appearance of various parts and organs.

A low suctorial fish would have no fenestra ovalis or stapes, and in the tadpole it is some time before these appear.

The low (urodelous) Amphibia have, in most cases, the upper hyoid element suppressed, sometimes it is present, serving as a rudimentary "*columella auris*."

In most Batrachia this part does not appear until after transformation, and in some kinds not at all. This part especially shows how the *individual* is gradually changed, and makes it clear why so many variations should occur in genera and even species.

With regard to the geographical distribution of the Batrachia, there are many things of importance which I have rather hinted at than expressed in this paper.

There is a sort of *facies* or character about the allied types of any great geographical region which makes me satisfied that certain external characters repeat themselves again and again in different parts of the world.

Thus the types of frogs that have dilated toes are evidently more nearly related to those with pointed toes of the same region than they are even to the broad-toed types of some distant region.

I should be inclined to derive the *narrow-backed* tree-frogs of Australia from the sharp toed frogs of the same region; the same with those of India, and the same with those of the nearctic and neotropical territories.

The *true* frogs ("Ranidæ") of India have many things in common, as also have the true frogs of North America; the same may be said of the sub-typical frogs, or "Cystignathidæ."

On the whole the European and Indian territories yield the highest kinds; Australia and South America the lowest and most generalised.

Mathematical Society, June 10.—Mr. C. W. Merrifield, F.R.S., president, in the chair.—The following communications were made:—On a binomial biordinal and the arbitrary constants of its complete solution, by Sir J. Cockle, F.R.S.—On the focal conics of a bicircular quartic, by Mr. H. Hart, M.A. —Preliminary note on a generalisation of Pfaff's problem, by Mr. H. W. Lloyd Tanner, M.A.—On the resultant of a cubic and a quadric binary form, by Prof. Cayley, F.R.S.—On the theory of the focal distances of points on plane curves, by Mr. W. J. Curran Sharp, M.A.—Geometrical note, by Mr. H. M. Taylor, M.A.

Linnean Society, June 3.—Prof. Allman, F.R.S., president, in the chair.—The secretary read a paper on the specific identity of *Scomber punctatus*, Couch, with the *S. scomber*, Linn., by Dr. Francis Day. The specimen on which this opinion is founded was captured on the coast of Cornwall in April last.—In a note on the anal respiration in the zœa larva of the decapods, by Marcus M. Hartog, he shows from an examination and study of living larvæ of *Cancer* that the terminal part of the rectum is slightly dilated, and possesses a rhythmic contraction and expansion duly associated with opening and closing of the anus. A clue to the ultimate transference of branchial respiration may perhaps be found in the Entomostraca, where in certain forms food is obtained by a current from behind forwards due to the movement of the setose or flat limbs immediately behind the mouth. Prof. Claus has shown that in *Daphnia* the said limb processes have a respiratory function, while this animal also possesses a well-marked anal respiration.—Mr. G. Murray made a communication on the application of the result of Pringsheim's recent researches on chlorophyll to the life of the lichen. Summarising Pringsheim's labours and taking into consideration the views of Vines, Geddes, and Lankester, Mr. Murray arrives at the following conclusion:—That we have in lichens fungal tissues as the body of the thallus and the chlorophyll screen in the gonidial layer; that is, the chlorophyll is in one system of cells and the protoplasm apparently affected by it in another, which is in contact. The light which traverses the chlorophyll-containing gonidial layer excites in the fungal tissues the decomposition of carbonic acid.—Mr. P. Herbert Carpenter, in giving the results of some researches of his in the form of a paper on the genus *Solanocrinus*, Goldfuss, and its relations to recent *Comatulæ*, stated that Schlüter was perfectly justified in uniting *Solanocrinus* with *Antedon*. The latter author does the same with *Comaster*, though to Mr. Carpenter, Goldfuss's description of this type appears to differ so much from all other Comatulæ that he prefers provisionally to regard it as distinct. Mr. Carpenter's researches on the crinoids in question are based on material obtained from the *Challenger* Expedition and a study of the fossil forms contained in the Woodwardian (Cambridge) and British Museums; he thus finds, on comparison of the living with past Jurassic, Cretaceous, and Tertiary forms, that variations in the development of the basals are useless as generic distinctions.

Chemical Society, June 3.—Prof. H. E. Roscoe, president, in the chair.—It was announced that a ballot for the election of Fellows would take place on June 17. The following papers were read:—On some products of the oxidation of paratoluidine, by W. H. Perkin. The present paper contains a study of the action of chromic acid on the above substance. Some beautifully crystallised products were obtained; one having the composition $C_{21}H_{21}N_3$, melting at 216 – 220°, and giving a magnificent blue colour with sulphuric acid; it has the characters of a base; a second base, rather less soluble, melting at 175° was also separated; it has the formula $C_{28}H_{27}N_3$. By using glacial acetic as a solvent for the chromic acid in the above reaction parazotoluene was formed.—On the detection of foreign colouring matters in wine, by Dr. A. Dupré. The true colouring matter does not dialyse; all the artificial colouring matters except alkanet dialyse freely, so that cubes of gelatine jelly soaked in the wine for forty-eight hours become scarcely tinged below the surface if the wine is pure, but if coloured with magenta, &c., the cube is stained to the middle. Alkanet is easily recognised by its absorption spectrum.—On the action of organozinc compounds upon nitrites and their analogues. I.—Action of zinc ethyl on azobenzene, by E. Frankland and D. A. Louis. In this reaction anilin is formed, much gas being evolved, consisting of 3 vols. of ethylene to 1 vol. of ethylic hydride. 70 grm. of anilin were obtained from 80 grm. of azobenzene.—II. On the action of zinc ethyl upon benzonitrile, by E. Frankland and J. C. Evans. Cyaphenine was the principal product of this reaction; this substance, by the action of strong hydrochloric acid in a sealed tube at 250°, is converted into benzoic acid and ammonia.—On the relation between the molecular structure of carbon compounds and their absorption spectra, by Prof. W. N. Hartley. The author has photographed the spectra of various substances; he concludes that no molecular arrangement of carbon atoms causes selective absorption, *i.e.*, gives absorption bands, unless three pairs of carbon atoms are doubly linked together in a closed chain. The most remarkable substance in this respect is anthracene, which, when diluted one in 50,000,000, gives a considerable and distinct absorption.—On a simple method of determining vapour densities in the barometric vacuum, by C. A. Bell and F. L. Teed. It consists of a modification of Hofmann's apparatus.—Mr. C. T. Kingzett made a verbal communication to the effect that he had recently investigated the question of the slow oxidation of moist phosphorus in air, and had obtained evidence that both ozone and hydroxyl were formed.

Zoological Society, June 1.—Prof. W. H. Flower, F.R.S., president, in the chair.—Mr. Sclater made some remarks on the principal objects he had noticed during a recent inspection of the Zoological Gardens of Berlin, Hamburgh, Amsterdam, the Hague, and Antwerp.—The Secretary exhibited a spider of the genus *Tegenaria*, which had been forwarded to him from Cape Town by Mr. J. H. Payne, of that place. It had been taken within three miles of Cape Town, on the back of a horse, which had subsequently died, as it was said from the effects of the bite. —Mr. G. E. Dobson exhibited some new and rare species of bats, amongst which was an example of a new species of the genus *Megaderma*, from Australia, proposed to be called *Megaderma gigas*, and remarkable for its large size.—Mr. Dobson made some further remarks as to the date of the receipt of the Dodo bones exhibited by him at a former meeting.—Lord Lilford exhibited and made remarks on some nests and eggs of the Flamingo, which had been taken in the marshes of the Guadalquivir, below Seville, in April, 1879.—Lord Lilford also exhibited some fine hybrid pheasants, between males of Reeves's pheasant and hens of the common pheasant.—Mr. E. W. H. Holdsworth read a note on the distribution of the crayfish (*Astacus*) in Spain.—Prof. F. Jeffrey Bell read a paper on some species and genera of the Temnopleuridæ, in course of which he described the method he had adopted in comparing different species, and species at different stages in growth; he also directed

especial attention to the differences in the size of the generation pores in *Amblypneustes formosus*, and discussed the specific characters of *Salmacis globator*.—A communication was read from Dr. A Günther, F.R.S., containing notes on a collection of mammals from Japan.—Mr. G. E. Dobson read a description of a new species of bat, of the genus *Natalus*, from Jamaica, which he proposed to name *N. micropus*.—Mr. A. W. E. O'Shaughnessy read the description of a new species of lizard of the genus *Uromastix*, from Zanzibar, which he proposed to call *U. princeps*.

Geological Society, May 26.—Robert Etheridge, F.R.S., president, in the chair.—Prof. Frederick Guthrie, F.R.S., Rudolf Hænsler, Ph.D., James Hulme, William Jolly, Charles Myhill, and Alfred George Savile, were elected Fellows of the Society.—The following communications were read :—The pre-carboniferous rocks of Charnwood Forest (Part III.; conclusion), by Rev. E. Hill, M.A., F.G.S., and Prof. T. G. Bonney, F.R.S.—In their former communications the authors had paid less attention (from want of time) to the northern part of the forest than to the rest. This district has during the last two years engaged their special attention. They had provisionally retained the name quartzite for the rocks exposed about Blackbrook, &c., probably the lowest visible on the forest. This name proves to be inappropriate, and they propose to call the group, which contains much fine detrital volcanic material, the Blackbrook Series. They have also reason to believe that the anticlinal fault is less than was supposed, and that we have here a fairly unbroken base for the forest rock already described. In this case there ought to be representatives of the great agglomeratic masses on the western side of the anticlinal (High Towers, &c.). The authors believe that they have found these, though as much finer and more water-worn detritus, in the greenish grits above Longcliff and Buckhill. The authors also believe that they have succeeded in tracing a coarse agglomerate with slate fragments round about three-fourths of the circumference of the forest. Further notes upon the district of Bardon Hill, Peldar Tor, and Sharpley are given, and the origin of the remarkable rock of the last, so like some of the Ardennes porphyroids, is discussed; the authors believe it to be a volcanic tuff, altered by the passage of water or of acid gases. Descriptions of the microscopic structure of some of the rock-fragments included in the coarse agglomerate and of some of the slates are given. Also a notice of two small outbursts of igneous rock of the northern syenite type, previously unnoticed, are mentioned.—On the geological age of Central and West Cornwall, by J. H. Collins, F.G.S. The author divided the stratified rocks of this district into four groups, as follows :—1. *The Fowey Beds*, mostly soft shales or fissile sandstones, with some beds of roofing-slate; no limestones or conglomerates. These beds cover an area of not less than eighty square miles, and contain numerous fragmentary fish-remains and other fossils, many as yet undetermined, the whole, however, indicating that the beds are either Lower Devonian or Upper Silurian. The strike of the beds is north-west to south-east, and they are estimated to be not less than 10,000 feet thick. 2. *The Ladock Beds*, consisting of slaty beds, sandy shales, sandstones, and conglomerates; no limestones and no fossils. They cover an area of more than 100 square miles to the west and south of St. Austell, strike from east to west, and overlie Lower Silurian rocks unconformably. They are estimated at from 1,000 to 2,000 feet thick. 3. *The Lower Silurians* consist largely of slates and shales, with some very thick conglomerates (one being at least 2,000 feet thick), some quartzites, and a few thin beds of black limestone. The quartzites and limestones have yielded fossils (chiefly Orthidæ) which are pronounced to be of Bala or Caradoc age by Davidson and others. The total thickness of these beds is estimated at 23,000 feet, and the fossils are found in the upper beds only. Instead of occupying only about twelve square miles, as shown on the Survey maps, they extend over nearly 200 square miles, and reach southward beyond the Helford River, and westward to Marazion. The strike of these rocks is from north-east to south-west. 4. *The Ponsanooth Beds* occur beneath the Lower Silurians, and unconformable with them (strike north-west to south-east); they are often crystalline, and are estimated at 10,000 feet thick. Each of these formations has its own set of intrusive rocks; each has been contorted and in part denuded away before the deposition of its successor. The various granitic bosses have been pushed through this already complex mass of stratified rocks without materially altering their strike, which does not in general coincide with the line of junction. The chemical effects of the igneous intrusions are generally considerable, and somewhat proportioned to their relative bulk.—On a second pre-Cambrian group in the Malvern Hills, by C. Callaway, D.Sc. F.G.S.

Anthropological Institute, May 25.—Edward B. Tylor, F.R.S., president, in the chair.—Dr. H. Woodward read extracts from a paper by Prof. J. Milne, F.G.S., of the Imperial College of Engineering, Yedo, on the Stone Age in Japan. The author described, from personal examination, many of the archæological remains in Japan. Kitchen-middens are abundant, and are ascribed to the Ainos, the ornamentation on the pottery resembling that still used by the Ainos of to-day. The shells and bones found in the middens were enumerated and described. The stone implements found in Japan include axes, arrow-heads, and scrapers. Many of these occur in the middens. The axes are formed generally of a greenish stone, which appears to be a decomposed trachytic porphyry or andesite. The Ainos used stone implements up to a comparatively modern date. Tumuli occur in many parts of Japan, as well as caves, both natural and artificial. Prof. Milne had opened one of the latter, and found the interior covered with inscriptions. The Japanese themselves make valuable collections of stone implements, old pottery, &c., the favourite notion among them being that such things were freaks of nature. Several fragments of pottery, shells, and other remains from kitchen-middens were exhibited.—Mr. C. Pfoundes read an interesting paper on the Japanese people, their origin, and the race as it now exists. Passing over the fabulous period, we find the Japanese commence their era and history about the same time as that of Rome, B.C. 660; the first Emperor, Mikado, or Ruler, established himself in the vicinity of Kiote, not very far from the present treaty ports Osaka-Kiogo. For centuries history teems with accounts of efforts to civilise the people, and the wild and intractable aborigines were gradually driven northward, until they settled in the North Island, where they still exist and form the bulk of the present inhabitants. Mr. Pfoundes exhibited a valuable collection of photographs and drawings in illustration of his paper, together with articles of Japanese manufacture and some fine specimens of tapestry.

Entomological Society, June 2.—Sir John Lubbock, Bart., F.R.S., president, in the chair.—Miss Georgiana Ormerod, of Isleworth, and Mr. Hy. Lupton, of Chapel Allerton, Leeds, were elected Ordinary Members.—Mr. M. J. Walhouse exhibited a collection of moths from Mangalore, on the Malabar coast, many of the species of which resembled palæarctic forms.—Mr. J. A. Finzi exhibited, on behalf of Mr. Lowrey, a bred specimen of *Arctia fuliginosa* which possessed only one antenna. The President stated that he had occasionally bred ants with only one antenna, and on one occasion had possessed a specimen with no antennæ at all.—The President also exhibited specimens of a new Australian ant received from Mr. Waller, which agreed with the genus *Myrmecocystus*, of Wesmael, in having an immensely distended abdomen, so that the insect actually serves as an animated honeypot.—The Rev. H. S. Gorham communicated the concluding portion of his Materials for a Revision of the *Lampyridæ*.

Victoria (Philosophical) Institute, June 8.—Annual Meeting.—The Right Hon. the Earl of Shaftesbury, K.G., in the chair.—Prior to the delivery of the address by Bishop Cotterill, D.D., F.R.S.E., the honorary secretary, Capt. F. Petrie, read the report, from which it appeared that the total number of Members was now 835.—The subject of the annual address was one aspect of the relation between the scientific and the religious view of the universe.

Vienna

Imperial Academy of Sciences, February 19.—The following among other papers were read :—On the relation of the muscle-current to local chemical changes of the muscle substance, by Dr. Biedermann.—On orthoethylphenol, by Drs. Suida and Plohn.—Theory of conic surfaces of the fourth degree with a double conic section, by Herr Ameseden.—Changes of form of electrical figures by magnets, by Prof. Reitlinger and Dr. Wächter.—On ventilation in schoolrooms, by Herr Nachtmann.—On the decomposition of nitrososulphhydantoin with bases, and on a new acid, nitrosothioglycolic acid, by Prof. Maly and Herr Andreasch.

March 4.—On the orbit of the planet Ino (173), by Dr. Becker.—Determination of the absolute velocity of current electricity from Hall's phenomenon, by Prof. v. Ettingshausen.

—On a law of the stimulation of terminal nerve-substances, by Prof. Mayer.—Contributions to the photochemistry of bromide of silver, by Dr. Eder.—Notices on the formation of free sulphuric acid, and some other chemical relations of gasteropoda, especially of *Dolium galea*, by Prof. Maly.—On the theory of normal surfaces, by Prof. Peschka.—On cinchomeronic acid, by Dr. Skraup.—On aldehyde resin, by Herr Ciamician.—On an extension of the limits of validity of some general propositions of mechanics, by Prof. Simony.—On oxycuminic acid and on the action of nitrous oxide on organic compounds, by Prof. Lippmann and Herr Lange.

March 11.—The orthogonal-axonometric contraction circle, by Prof. Pesar.—Electrolysis of organic substances in aqueous solution, by Prof. Habermann.—Action of oxalic and sulphuric acid on naphthol, by Herr Hönig.—On dipropyloresorcin and some of its derivatives, by Herr Kariof.—On idryl, by Dr. Goldschmiedt.—On direct introduction of carbonyl groups into phenols and aromatic acids, by Herr Senhofer and Herr Brunnen.—Remarks on Cauchy's theory of double refraction, by Prof. v. Lang.—Determination of path of comets discovered at Pola in 1879, by Herr Palisa.

March 18.—Heliotropic phenomena in the plant kingdom (second part), by Prof. Wiesner.—On the projective construction of curves of the second order, by Prof. Binder.—On Sturm's series, by Prof. Gegenbauer.—A hydraulic motor, by Herr Kauer.—The alteration of molecular weight and molecular refractive power, by Prof. Janovsky.—On the tannic acid of oak-bark, by Herr Etti.—On some tertiary echinida from Persia, by Herr Fuchs.—Sulphur compounds of chromium, by Prof. Lieben.—Behaviour of bone gelatine in dry distillation, by Dr. Weidel and Herr Ciamician.—On the determination of the halogens in chlorates, bromates, and iodates, by Herr Fleissner.

April 8.—The following among other papers were read:—Theory of motion on developable surfaces, by Herr Wittenbauer.—The inflorescences of Marchantiaceæ, by Prof. Leitgeb.—On the magnetic action on fluorescence light excited by the negative discharge in a vacuous space, by Prof. Domalip.—On discrete vortex lines, by Dr. Marguess.—Contributions to the photochemistry of bromide of silver, by Dr. Eder.

PARIS

Academy of Sciences, June 7.—M. Edm. Becquerel in the chair.—The following papers were read:—On a bromised derivative of nicotine, by MM. Cahours and Etard. The formula is $C_{20}H_{14}N_2Br_4$.—Geological history of the English Channel (first part), by M. Hébert.—M. Daubrée gave a *résumé* of a study entitled "Descartes, one of the creators of cosmology and geology." Descartes considered all celestial phenomena as simple deductions from laws of mechanics, affirmed the unity of composition of the physical universe, perceived the capital *rôle* of heat in formation of our globe, &c.—M. du Moncel presented a third edition of his work on the telephone, microphone, and phonograph.—M. Chancel was elected correspondent in chemistry in place of the late M. Favre.—Theorems on the decomposition of polynomes, by M. Carrère.—Result of treatments of vines attacked with phylloxera, by M. Boiteau. The vines treated for three years past (with sulphide of carbon) are thriving beautifully. Infected vines over fifteen to twenty years old, which cannot renew their radicular system, should be replaced by young plants. The best method of application is that in parallel lines, with doses of 20 gr. per square metre applied in two or three holes. The sulphide even seems to stimulate the vine.—New generation of the surface of the wave and various constructions, by M. Mannheim.—On ternary cubic forms, by M. Poincaré.—On irreducible functions according to a prime modulus, by M. Pellet.—Remark relative to two integrals obtained by Lamé in the analytical theory of heat, by M. Escary.—On the partition of numbers, by M. David.—Direct measurement of the interior resistance of magneto-electric machines in motion, by M. Carnellas. The induction of the electro-magnets and the metallic cheeks is obviated by rotating the (Gramme) ring mounted carefully with its brushes on wooden supports, and the effects of terrestrial induction are avoided by opposing to each other these effects in two similar Gramme rings, mobile under the same conditions, with axes parallel. The ring (at rest or rotating) is made the fourth side of a Wheatstone bridge formed by Siemens' universal galvanometer. The resistance of the ring in motion (450 turns per minute) shows an increase of 25 per cent. on that of the ring at rest.—Transformation of gunpowder in the metallic cases of infantry cartridges, by M. Pothier. A diminished velocity of balls of cartridges that have been long charged, and diminished accuracy of fire, are accounted for by a proved chemical decomposition of the powder in contact with the metallic case, the quantity altered varying according to atmospheric influences, especially moisture, at the time of manufacture or during storage. Experiment proved zinc to have most action, then followed copper. Lead, tin, and iron affect the powder less. High temperature accelerates the transformation if the powder is moist.—Optical arrangement for firing within covered batteries, by M. de Fraysseix. By means of a lens and screen the artilleryman is enabled to take better aim. M. Ed. Becquerel called attention to previous devices of the same kind.—On colloidal oxide of iron, by M. Magnier de la Source. The composition of the soluble ferric hydrate is that of the normal hydrate.—On a new sulphate of alumina (sesquibasic sulphate of alumina), by M. Marguerite. One method of preparation is decomposition of alum of ammonia by heat. Three others are indicated.—Action of chlorine on sesquioxide of chromium, by M. Moissan.—On a combination of allylic alcohol with anhydrous baryta, by MM. Vincent and Delachanal.—On the fixity of composition of plants; ratio between the fecula, phosphoric acid, and mineral substances in potato, by M. Pellet. While these show constant ratios there are great differences in the proportions of the chief alkalis, lime and potash; but there is equivalent substitution of these alkalis, so that the quantity of sulphuric acid necessary to saturate all the bases is sensibly the same. Silica and nitrogen vary pretty largely.—Analysis of the seeds of beet, by MM. Pellet and Liebschutz.—Disinfection and conservation, from an agricultural point of view, of animal matters, and notably blood, by use of bisulphate of alumina and nitric acid, by M. Vautelet. They act by coagulation, &c.—On the physiological effects of erythrophleine, by MM. Lee and Bochfontaine. It acts both on the heart and the respiratory apparatus, and may prove a useful clinical agent.—On some anatomical characters of Chiroptera of the genus *Cynonycteris*, by M. Robin.—On the metamorphosis of *Perosopestona*, by M. Vayssière.—On a peculiar modification of a parasitic Acarian, by M. Megnin. The eggs of a *Cheyletus*, on an American Grosbeak, were found protected by fine tissue, like that furnished by certain Arachnides.—Helminthological observations and experimental researches on the disease of work men in the St. Gothard, by M. Perroncito. The numerous workers who have become anæmic have been preyed upon by certain small worms, and this quite explains the anæmia. A similar malady was observed in making the Mont Cenis tunnel.—M. d'Abbadie presented a work by Mr. Knipping on the cyclones of 1878 in the China Seas.

CONTENTS

THURSDAY, JUNE 24, 1880

A STEP BACKWARDS

WE are glad that Sir John Lubbock has given notice that he will call attention to the Education Code and move a resolution, unless indeed the Government themselves are sufficiently wide awake, patriotic, and liberal in its best sense, to step in and prevent Lord Norton's resolution in the House of Lords the other day from attaining the issue desired by the educational obstructionists. Lord Norton's hostility to popular education is notorious, and on Friday he had the honour of being supported by several reverend bishops, who are supposed officially to yearn after the highest welfare of the people. The effect of Lord Norton's resolution would be to cut out everything like real education and training from our elementary schools, and leave nothing but the minimum of instruction in the three R's. It seems hard to have to go over the old ground again, and to show that the pittance of education which Lord Norton and those who side with him would allow the vast majority of the children of the nation, is really no education at all. The objection apparently of Lord Norton to the retention of the specific subjects of the fourth schedule is that their introduction has been too successful; that in some schools the talents of a few pupils under this system have been so developed that they have been continued at school beyond the age of fourteen. Considering the ample opportunities which charity has provided for the education of the children of the class to which Lord Norton and his supporters belong, it seems to us mean in them to grudge the pittance expended by the country in encouraging a few hundred clever boys of the humbler classes to pursue their education to a degree for which they have shown special aptitude. We are especially surprised to find among the supporters of Lord Norton's motion the Duke of Richmond and Gordon, who thus condemns the very code which was drawn up under his auspices and which was worked under his superintendence for five or six years without any apparent suspicion on his part that it was not the best possible of all codes. Of course our enlightened statesmen would never stoop to degrade a subject of such national importance into a party question, and therefore the Duke of Richmond and the other enlightened and reverend supporters of the persistent opponent of popular education, did not surely realise the effects of their vote. The real aim of Lord Norton's resolution, there can be no doubt, is to stifle all training in science out of elementary education. We trust Sir John Lubbock will have an opportunity of speaking on the subject in the House of Commons, and reminding our legislators of some of the facts in his impressive speech of 1877. They evidently require to be reminded of what the real object of education is. Mere reading, writing, and arithmetic is but a poor and inefficient equipment for those who will have throughout life the hardest struggle with their physical surroundings. Crime and disease, it has been again and again proved, are more the result of ignorance than of anything else—ignorance, not of the three R's so much as ignorance of our own bodies and of the laws of that nature by which we are surrounded and of which we form part. In a former discussion in Parliament on this subject Mr. Playfair showed that many people were appalled by the mere name of science as connected with education, as if it were something beyond the comprehension of any but a select few, and far too remote from human interests to be of any use in a system of elementary education. But Mr. Playfair also showed that what was meant was merely natural knowledge, a knowledge of the facts and laws of nature, a knowledge of our own bodies and of the things outside our bodies with which daily every one comes in contact. In the speech already referred to by Sir John Lubbock, and reprinted in his "Political Addresses," he shows that grammar and even history, as ordinarily taught, are far more difficult and much less interesting than the elements of natural knowledge, which he maintains ought to be introduced into our elementary schools. Much more, he shows, could be advanced against the utility of teaching grammar than against teaching the elements of physiology or domestic or political economy; and history, as taught in most text-books, is a farrago of figures, crimes, murders, and battles. Lord Norton is evidently so completely ignorant of the real nature of science—which has to do with tangible, hard, every-day facts—that he thinks all that is necessary might be learned from a judiciously compiled reading-book. The fact is no book of any kind need be required by a competent teacher, and the whole aim and end of science teaching would be missed if it dealt with words and not things.

If it is desired to turn out men and women with well-trained, observant minds, fitted to grapple with the circumstances of the every-day life of the bulk of the people of this country, then the education which results from an acquisition of some of the most elementary laws and facts of nature is absolutely necessary. Moreover it has been clearly shown that in schools where a little science is properly taught the pupils are much further advanced as readers than in schools where there is no variety apart from the old-fashioned three R's. We cannot believe that Lord Norton's resolution will meet with any support outside the House of Lords; should it reach the House of Commons we are sure that body will have too much respect for the bulk of its constituents to insult and injure them by approving of any such retrogressive step.

FRESHWATER RHIZOPODS OF NORTH AMERICA

United States Geological Survey of the Territories—Freshwater Rhizopods of North America. By Joseph Leidy, M.D., Professor of Anatomy in the University of Pennsylvania and of Natural History in Swarthmore College, Pennsylvania. (Washington: Government Printing Office, 1879.)

THE scientific history of the freshwater rhizopods begins only a little anterior to the Declaration of Independence. Rösel (1755) knew of the existence of such forms, which puzzled him. Linnæus (1760) named one of them *Volvox chaos*;—*polymorpho-mutabilis*, the form of whose body was *Proteo inconstantior*. But with the increase in the powers of the objectives used with the microscope,

so did the knowledge of these forms increase. Ehrenberg and Dujardin led the way to a brilliant series of discoveries, which have been continuous, and never more numerous than during the last twenty years.

One protozoon was on the roll-call of the *systema naturæ* —who could count the vast multitude known to us now? The very list of the provisionary classes and sub-classes would be a long one.

On some of these classes splendid monographs have been written, among which those of Stein, Carpenter, Claparède, Haeckel, Wallich, and Brady may be mentioned, while the authors of papers on special genera and species would be too numerous to quote.

Most of the authors referred to have worked among the European forms, but Carter added greatly to our knowledge of those to be met with in the Island of Bombay. Africa and America were unknown countries; while the former still remains so, the persevering efforts of Dr. Joseph Leidy for the last ten years have gradually unfolded to us the rhizopodal wealth of North America, and have culminated in the publication of the finely-illustrated work that we proceed to notice.

As preliminary we are reminded that there is no very fixed system of classification for this class. Dr. Leidy treats of the fresh-water species only, as found in the orders Protoplasta, Heliozoa, and Foraminifera, the first two being commonly designated "Freshwater Rhizopods." These, writes Dr. Leidy, are to be found almost everywhere in damp or wet, but not over shaded positions; they are especially frequent and abundant in comparatively quiet waters, which are neither too cold nor yet too much heated by the sun. They are to be found among moss in spongy places or on damp rocks. They hide away among sphagnum-leaves, at the roots of sedges and grasses on the bark of trees. Once, we remember, Dr. Leidy got quite a store of them in the fork of an old apple-tree. Sometimes a depression or fissure in a rock, sometimes even the crevice of a wall or of the pavement, affords them space enough. We have taken them almost at the equator. Dr. Wallich has described many from within the Arctic circle. The favourite habitation of many forms is the light superficial ooze at the bottom of still waters. If this be gently collected, there they will be found grazing among the desmids and diatoms fond of such quarters. The dark deep mud that will be found below this it is as well not to stir; it is a layer in which life turns to death, and its odour is never pleasant. But again, these rhizopods are to be found in that creamy, flocculent matter that half floats on the surface of great pools. The expert collector will soon get to know the difference in these "creams"—some so rich in treasures, some containing nothing but dead cells and empty lorica; then again Dr. Leidy found these rhizopods in no place in such profusion, number, and beauty of form as in sphagnous bogs, living in the moist or wet bog moss (*Sphagnum*). "Sometimes he found this moss actually to swarm with multitudes of these creatures of the most extraordinary kinds and in the most highly-developed condition. A drop of water squeezed from a little pinch of bog moss has often yielded scores of half a dozen genera and a greater number of species." "Frequently, however," he adds, "the sphagnum of many localities contains comparatively few rhizopods, though I have rarely found them entirely absent from the moss." In Ireland the very reverse of this seems to hold true, and the exceptional multitudes have not yet turned up.

Dr. Leidy's volume is issued under the modest title of a "Report," so that it seems desirable to mention that it forms a large quarto volume of 324 pages, illustrated with 48 coloured plates. The printing and paper of the volume are simply perfection, like, indeed, most of the work issued from the Government printing-office at Washington, and brought out under the superintendence of Dr. F. V. Hayden. It forms one of the volumes of the United States Geological Survey, and its publication betokens an enlightened zeal on the part of the United States geologist in charge. As to the illustrations, we think the author quite unduly hard in his estimate of them. He says: "The illustrations accompanying this work, done in chromolithography, are not equal in execution to my desire," and he regrets the absence from the States "of those accomplished artists from Germany and France." To our mind, as chromolithographs, the illustrations are excellent. The drawings are recognisable at a glance. The slight hardness in outline and sharpness of colouring are not defects to be made over much of, and we feel sure that these plates will be for the most part recognised as good and excellent representations of the forms described.

There are about seventy-five species, including those of all orders, specially described in this volume, and it is a pleasure to note how few new genera are proposed. Speaking in general terms, Prof. Leidy seems to believe in there being a very large range of variability in the species, but it is not improbable that a more lengthened study of the forms might considerably modify his views. Any discussion on such points would be out of place in the present notice. A controversy as to what is a species, what a variety, would seem captious over a book quite full of the facts in nature as Dr. Leidy found them, and from which he leaves one in full confidence to draw their own opinion.

One very lovely form to this only known from North America is called by Dr. Leidy *Hyalosphenia papilio*. It is doubly interesting as marking an era in its describer's life. It is common and at times exceedingly abundant in moist bog or sphagnum, or sphagnous swamps, but it is not found in ponds unless accidentally. "No other lobose rhizopod has more impressed me with its beauty than this one. From its delicacy and transparency, its bright colour and form as it moves among the leaves of sphagnum, desmids, and diatoms, I have associated it with the idea of a butterfly hovering among flowers. From its comparative abundance, the readiness and certainty with which it may be obtained and observed, and from its transparency, which allows its structure to be well seen, it is peculiarly well adapted for the study of the life-history of its order; I have collected it from early spring to late autumn, and have retained it alive in sphagnum in a glass case in winter. This interesting rhizopod, found together with a profusion of other remarkable microscopic forms of both animal and vegetable life, of which many are novel and yet undescribed, recalls pleasing recollections of excursions into the sphagnous bogs, cedar swamps, and pine barrens in the southern region of New Jersey. These localities have special charms for the botanical

student, on account of the diversity of beautiful and interesting plants they produce. In proper season, in most places, they are redolent with the rich perfume of *Magnolia glauca* and the fragrance of *Clethra alnifolia.* In early spring the ground is adorned with bright patches of the little *Pyxidanthera barbulata*, and the sand myrtle (*Leiophyllum buxifolium*). Later the swamps display an abundance of *Helonias bulbata*, and still later many other liliaceous plants, *Zygadenus limanthoides*, *Narthecium americanum*, besides more common ones. Rich are these woods and swamps in genera of orchids. On the dry banks grow Vaccinia and other ericaceous plants, amidst which are conspicuously to be seen the spikes of white flowers of the grassy-looking *Xerophyllum asphodeloides*, while the bogs below are as conspicuously dotted with the curious green and purple pitcher plant (*Sarracenia purpurea*) nestling among sphagnum and entangled among sundews." This rhizopod was first noticed by Prof. Leidy some thirty years ago, but it was not until 1873, on the fiftieth anniversary of his birth, that he commenced to study the rhizopods with the assistance of the microscope. He had scarcely begun to do so until he came again across this form, and he then named it as *Difflugia papilio.* It was the re-discovery of this beautiful form which he tells us impelled him to pursue the investigations which built up the material of the present work.

The greater part of this volume is taken up with the details of the "Protoplasta," of which a few species are for the first time described, but most of the peculiarly American species figured have been already described by Dr. Leidy in the *Proceedings* of the Academy of Natural Sciences of Philadelphia. In many of the species the endosarc was bright green from the presence of chlorophyll (spelled chlorophyl in this volume throughout). The forms recorded as belonging to the "Heliozoa" are not very numerous, and among them no doubt a good deal of work remains to be done. A Vampyrella form is included among these, but Dr. Leidy could detect no nucleus. Of the free forms the most interesting are *Actinophrys sol*, *Heterophrys myriapoda*, *Raphidiophrys viridis*, *Diplophrys Archeri*, *Actinosphærium eichornii*, and *Hyalolampe fenestrata*, while of the attached forms only *Clathrulina elegans* was met with, it is beautifully figured.

Of the foraminiferous order one species of Gromia (*G. terricola*) is described and figured, and a genus Biomyxa is established for a rather problematic form, consisting of what might prove yet to be the plasmodium of a fungus. No forms related to Chlamydomyxa were met with, but we forbear to linger further over special details, and we close a volume which will henceforth be as useful to the investigator of these forms in Europe as in America.

E. P. W.

THE RECENT PROGRESS OF ENGLISH PHILOLOGY

The Journal of Philology. ix. 17. (Macmillan and Co., 1880.)

The American Journal of Philology. i. 1. (Macmillan and Co., 1880.)

THE establishment of a new philological journal, devoted more especially to the study of the classical languages, seems a fitting occasion for reviewing the present condition of philology, in the narrower and German sense of the word, among English-speaking scholars. A great change has come over the study of Latin and Greek during the last half century, and the old-fashioned scholarship whose highest aim was the composition of faultless verses seems likely soon to become a thing of the past.

The change has been largely due to the rise and growth of comparative philology. The conception of law has been introduced into the study of speech, and we have learned that in language as in nature there is nothing arbitrary and capricious, that what now exists is the result of a long and gradual development determined by ascertainable conditions and causes. Above all we have come to know that we cannot pick out any one language as superior to all others in the same way that we pick out a particular literature as superior to other literatures; the only test in fact of the worth of a language is its greate or less capacity for expressing thought. The thought, it is true, may be poor; but this is the fault of the thinkers, not of their language.

Latin and Greek grammar has thus been brought down from the lofty pedestal on which it once stood and shown to be neither better nor worse than the grammar of any other form of speech. But in return a new spirit of life has been breathed into it. It is no longer a collection of arbitrary rules and lists of words compiled from the literary usages of a certain number of writers. Its rules have been explained, its words traced historically to their earlier forms, and the grammar of the classical tongues has once more become a living organism, developing and changing in accordance with scientific laws like the grammars of modern languages.

Along with this truer conception of Greek and Latin grammar has come a truer conception of the Greek and Latin languages themselves. We have come to realise that like our own mother-speech they consisted of sounds not of letters, of living words not of the written symbols that stood for them. A dead language differs from a spoken one only in that we know less about it. We cannot lay down that the particular form of language used by certain literary men at a particular period is either Greek or Latin. If we would understand what Greek really was we must study it in its various dialects, must examine it in the inscriptions which represent the language of everyday life more faithfully than an artificial literature, and by the help of comparison and induction must trace its history back to that early time when it was still but a dialect of the common Aryan tongue. So, too, we must divest ourselves of the notion that the idiosyncracies of a few literary men alone constitute correct Latin, and seek the true character and history of the language rather in the inscriptions which modern research has brought to light.

Classical philology has further felt the influence of the comparative method of linguistic science even on its purely literary side. We have ceased to regard the works of the classical writers with the wondering awe of the scholars of the Renaissance, or to determine their relative merits by the conventional standard of traditional or subjective criticism. Manuscripts are now carefully examined and collated, the accuracy of tradition is questioned and the genuineness and date of the books that have come down to us are sharply tested. We can

no longer accept any statement, no longer receive any reading, however strongly supported by authority or backed by ancient tradition, unless it be corroborated by the potent instrument of comparison. The modern scientific method is the bar before which our classical studies must all be brought.

The truth of this may be seen at once by comparing the contents of our modern philological periodicals with those that were published at the beginning of the present century. The material still remains the same, but the spirit, the method, and the aims have all been changed. In this, as in the science of language itself, Germany has led the way; but the example of Germany has now found able imitators both in this country and in America. The English *Journal of Philology* has been too long in existence for its merits to need more than a passing recognition, and the *American Journal*, the first number of which has just appeared under the editorship of Prof. Gildersleeve, promises to be a worthy rival of its English forerunner. At present, indeed, most of its articles have a touch of "rawness" inseparable from a new venture, but a large part of it is occupied in a most useful way by an analysis of the articles that have been published in kindred foreign serials. This is a feature that might be imitated with advantage by the English *Journal*. Both publications admit Oriental and general as well as purely classical subjects, and an article in the last number of the English *Journal* by Prof. Robertson Smith on "Animal Worship and Animal Tribes among the Arabs and in the Old Testament," is marked by his usual learning and acuteness. He shows in it that Mr. Maclennan's theory of a primitive totemism in connection with polyandry is fully confirmed by the early beliefs and practices of the Semites. A new light is thus cast upon the beginnings of Semitic religion, and obscure allusions in the Old Testament are cleared up.

A. H. SAYCE

OUR BOOK SHELF

Fern Etchings: Illustrating all the Species of Ferns Indigenous to the North-Eastern United States and Canada. Second Edition. By John Williamson. (Louisville, Ky., 1879.)

A HANDSOME book, consisting of etchings, with accompanying letter-press descriptions, of sixty-eight species or varieties of ferns, natives of the northern part of the American continent. The drawings are well executed and characteristic, giving a faithful idea of the general habit of the fern, though without any enlarged details; and the accuracy of the descriptions is insured by borrowing them from Gray's "Manual" or Eaton's "Ferns of North America." Of the species depicted, including all that are natives of the Northern United States and Canada, twenty-two, or about one-third, are also natives of the British Isles. The southern limit for the volume appears to be Virginia and Kentucky. The volume is an elegant ornament to the drawing-room table.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

A Fourth State of Matter

IN the very interesting communication from Mr. Crookes on "A Fourth State of Matter," which is contained in NATURE, vol. xxii. p. 153, there is a paragraph at the end which advances, as it seems to me, some most disputable propositions.

Like many other questions of modern science, the question he raises is to a very large extent a question of definition. But questions of definition are questions of the very highest importance in philosophy, and they need to be watched accordingly.

Speculating on the ultimate conceptions of Matter which are affected by the discovery of it in "a fourth condition," Mr. Crookes says: "From this point of view, then, Matter is but a 'mode of motion.'"

It has never appeared to me that this well-known phrase is a very happy one, even as applied to Heat. It is possible, of course, to consider Heat from this point of view. But then it is equally possible to consider all other phenomena whatever from the same point of view. Not only Heat, but Light, Sound, Electricity, Galvanism, and Sensation itself in all its forms, may be regarded as "modes of motion."

But at least in the application of this phrase to Heat there is an intelligible meaning, and not a mere confusion of thought. But as applied to Matter—as a definition of our ultimate conception of Matter—it appears to me to confound distinctions which are primary and essential. "Motion" is an idea which presupposes Matter and Space. Motion has no meaning whatever except the movement of Matter in Space. To define Matter, therefore, as a "mode of motion," is to define it as Matter in a state of motion. But this definition necessarily implies that Matter can also be conceived as without motion, and accordingly Mr. Crookes is obliged to confess that "at the absolute zero of temperature inter-molecular movement would stop," and that after that, Matter would remain with all the "properties of inertia and of weight."

Again, Mr. Crookes says: "The space covered by the motion of molecules has no more right to be called Matter than the air traversed by a rifle-bullet can be called lead." No doubt this is true; but it implies what is not true, that the common idea of Matter is nothing but "the space covered by the motion of molecules." The popular ideas attached to words of primary significance may not be always adequate or complete. But in my opinion they are generally much more near the truth and more accurately represent the truth, than most of the phrases which scientists are now inventing in the region of transcendental physics.

These phrases have their value and their interest as representing special and partial aspects of phenomena. But I hold that the unconscious metaphysics of human speech are often the deepest and truest interpretations of the ultimate facts of nature.

The Fine Wire Telephone

I HAVE just read in NATURE, vol. xxii. p. 138, an abstract of the *Proceedings* of the Royal Society of London, giving an account of a new form of telephone receiver devised by Mr. Preece.

It happens, very curiously, that I was led independently to construct a practically identical instrument, with which I have been experimenting for some time in the laboratory of my colleague, Prof. Tait, and which was exhibited in action at the last meeting of the Royal Society of Edinburgh, before I was aware of Mr. Preece's invention.

The experiments of Mr. Preece and myself have been to a considerable extent anticipated by some results given in a paper by Dr. Ferguson (*Proc.* R. S. E., 1877-78, pp. 628 *et seqq.*), of which I was unaware when I made my own experiments.

It is true that Dr. Ferguson has not applied his apparatus to the transmission of music or of articulate sounds, as has been done by Mr. Preece and myself; but he made the practically very important step of attaching a mechanical telephone to the wire which conveys the varying current, and has thus rendered the observation of De la Rive's sounds in iron and other metals both easy and certain.

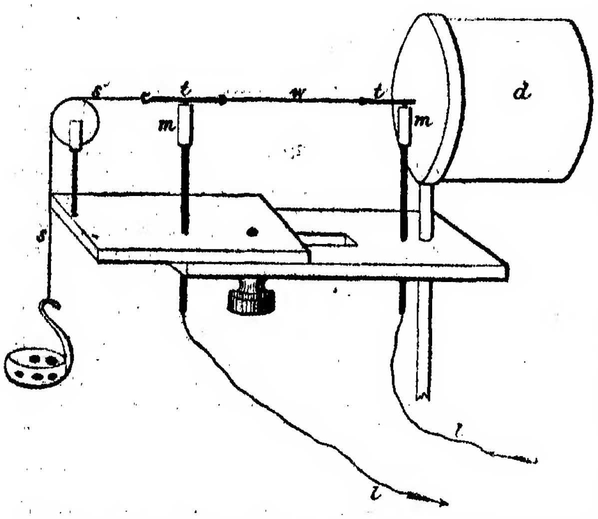
In Dr. Ferguson's paper will also be found a most important result, which I have verified since he drew my attention to it, viz., that sounds can be produced in fine wires generally by induction currents of very feeble total heating effect.

As to the theory of the action of this new kind of receiver, I agree with Mr. Preece that in weakly magnetic metals generally it is due to heating effects. I had been discussing with Mr. Blyth the theory of his receiver (described in NATURE, vol. xix. p. 72), and it was as an illustration of the explanation of all kinds of microphone receivers, suggested by his beautiful experi-

ments on loose contacts, that I thought of the experiment in question. My idea was to replace his heated point of metal by a continuous portion of the circuit which should act in the same manner. It was obvious that this part must be of small diameter to secure resistance enough to make the extension of the wire due to the variation of the heating effect sensible; and to insure that the cooling should be rapid enough to allow a musical note to be produced.

I had reason beforehand to believe that the second condition could be fulfilled in practice; because I had found in my experiments on Ohm's Law (*Reports*, British Association, 1876, p. 58, *et seq.*) that, when currents of different strengths alternated very rapidly in a fine wire, the cooling was so rapid that the resistance was sensibly greater during the passage of the strong current than it was during the passage of the weaker.

The accompanying figure represents the apparatus with which I worked. I generally used a microphone attached to a violin, belonging to Mr. Blyth, for a transmitter. In this way music was reproduced so as to be audible all over Prof. Tait's large class-room. For reproducing articulate speech I have found a small mica diaphragm, like that used by Edison, Blyth, and others, best; words spoken to the violin are reproduced in this way quite intelligibly, but as I do not possess a good microphone transmitter, I have not experimented much in this direction.



w, fine wire; *t t*, thicker copper terminals; *m m*, mercury cups over which *t t* pass; *s s*, string kept tight by small load; *l l*, line wires to microphone; *d*, drum head which distributes the sound.

So far as the limited supply of fine wire permitted, I had arrived substantially at the same results as Mr. Preece regarding the length and tension of the wire. My best results were got with a very fine silver-palladium wire given me by Prof. Tait; with it I could see the string s s move in time with the swell of the music. I also used a thicker and shorter platinum wire, heated by the current to a dull red, during silence; it was beautiful to see this wire burst into a bright glow when there came a prolonged note, more especially a high one.

Dr. Ferguson, in the paper above referred to, regards these effects as not due to heating (although he seems to think they follow the same law), but as being molecular in some other sense not very clearly defined. Except in the case of iron,[1] I do not see at present any necessity for so regarding them. The fact that induction-currents of small heating effect will produce them is not conclusive; for it must be remembered that it is not the *whole* heating effect, but the *variation* of it during a very short interval that is in question, and some calculations from rough data in my possession have led me to think that there would be no inconsistency in explaining Dr. Ferguson's ticks and the speech and music in Mr. Preece's experiment and my own as due to the same cause. I think also that it is quite possible that we might be able to hear ticks in a wire far too thick for the reproduction of music.

I have begun some experiments with a view to throw some light on questions of this kind. Possibly in the meantime Dr. Ferguson, Mr. Preece, or some other experimenter may be able to produce facts that settle the matter beyond the possibility of doubt.

G. CHRYSTAL

15, Chalmers Street, Edinburgh, June 12

[1] Iron may be anomalous on account of its powerful magnetic properties; and Prof. Tait has suggested that, at a certain high temperature, it may, for well-known reasons, be incapable of producing these effects altogether.

The Aurora Borealis and its Colours

IN reference to Mr. Backhouse's letter last week (p. 145) we have nowhere stated that "similarity in colour in electric discharges is sufficient to indicate similarity of constitution, even when their spectra are quite unlike." If Mr. Backhouse will again read our paper on the Aurora, he will see that we say that in the same gas the colour of the discharge varies with the degree of exhaustion. In the *Phil. Trans.*, 1878, part 1, we have shown also that in the same gas at the same pressure the colour of the discharge varies with the amount of current; at pp. 180–181, for example, the strata in hydrogen at a pressure of 1·2 mm., 1579 M, were of a cobalt blue with a current of 0·019940 W, and pink with a current of 0·008504 W. In the index at p. 239 are given several references to the same phenomena; and at p. 240 references are given to a number of observations on the "spectra of strata and of glow on terminals."

It is very difficult to say for certain whether the red is below or above the green in aurora displays, by eye estimation; for although apparently above it may be really below. We adhere to our opinion that the red is at the lower level.

WARREN DE LA RUE
73, Portland Place, W. HUGO MÜLLER

On some Points Connected with Terrestrial Magnetism

IN NATURE, vol. xxii. p. 147, our friend Prof. Balfour Stewart makes the following statement in paragraph γ:—

"Above this again we have the lower strata of the atmosphere, which are non-conductors, while above this we have the upper strata, which are conductors."

We venture to think that our researches prove that air cannot, at any degree of attenuation, be considered as a conductor of electricity in the ordinary acceptation of the term.

In the *Phil. Trans.*, Part I. p. 168, after citing a number of experiments bearing on this point, we say:—"These observations show clearly that the discharge through rarefied gases cannot be at all analogous to conduction through metals; for a wire having a given difference of potential between its ends can permit one—and only one—current to pass; whereas we see that with a given difference of potential between the terminals of a vacuum tube currents of strengths varying from 1 to 135 can flow. We are therefore led to the conclusion that the discharge in a vacuum tube does not differ materially from that in air and other gases at ordinary atmospheric pressure, that it is, in fact, a disruptive discharge."

In Part III. of our researches (an abstract of part of which appears in the same number of NATURE), *Phil. Trans.*, vol. clxxi. p. 82, we sum up a series of experiments on the electric discharge in various gases by stating that the same law holds good for a constant pressure and varying distance between flat terminals as for a constant distance and varying pressure, the obstacle in the way of a discharge being, up to a certain point, as the number of molecules intervening between the terminals.

The hyperbolic curves laid down to represent the observations in each case are perfectly continuous, and show no break from the condition of a non-conductor to that of a conductor.

Calcareous Concretions in Timber

IN NATURE, vol. xxi. p. 376, I observe that in a remark of the reviewer, and also in an extract from Mr. Ball's "Jungle Life in India," the occurrence of concretions of lime in trees is spoken of as a rare and novel phenomenon. That *Terminalia tomentosa* contains calcareous matter has long been known to natives, and a reference to Tennent's "Ceylon," i. 99, will show that they make a practical use of their knowledge by using the ashes of the bark as a substitute for lime, to chew with betel. Another southern tree which contains an alkali in its bark is *Avicennia tomentosa*. It generally grows along the margins of backwaters,

and has a most wonderful provision for preventing the erosion of the banks and for adding to the dry land. It is a squat bushy tree, and round the stem, to an extent equal to the spread of its branches, it sends up thickets of straight shoots a foot or two high. These, when the tide is up or the water in flood, catch all the stray branches, leaves, grass, &c., that may be floating about, and also promote silt. By this contrivance, therefore, not only are the banks protected from the distinctive action of water, but also raised and consolidated. Again, as regards Mr. Stoney's observation of calcareous masses in timber, which was brought to the notice of the Asiatic Society of Bengal in 1870 as a fresh discovery, it seems strange that the learned body in question did not know that the existence of such concretions, so far from being very rare, is an occasional and well-known phenomenon. Thus, in the *Madras Journal of Literature and Science* for April-September, 1858, page 142, Prof. Mayer gives a qualitative analysis of a concretion of the kind found in a teak log. It consisted chiefly of magnesia, with potash, lime, silica, and a trace of iron. The substance, he says, "Must be looked on as a mixture, and not a true chemical compound." Again, he observes, "as a whole the substance thus hardened is insoluble in cold, and but slightly so in water of higher temperature. At 212°, however, there is sensible action after a time. In diluted hydrochloric acid solubility ensues, hastened by increased temperature. Solution is attended by slight effervescence, some carbonic acid being liberated." He then proceeds to give an explanation of the process by which such mineral matters may be taken up from the soil and deposited in the tree. So far as I know the occurrence of such concretions in India was first brought to notice by Lieut., now Col. Hawkes, of the Madras Army, in 1858. He had seen them only in teak logs, and remarked that they generally occur "in what carpenters call a shake in the wood, but with this exception the logs are perfectly sound, and no communication whatever with the external air has been observed."

Government Central Museum, Madras, May 13

Remarkable Discovery of a Murder in Bermuda

THE following account of a murder which was committed in Bermuda in the autumn of 1878 is taken from a letter written to Gen. Sir J. H. Lefroy, C.B., F.R.S., lately Governor of these islands, and author of the "Annals of Bermuda," by the Attorney-General of the islands, Mr. S. Brownlow Gray. The mode of discovery of the crime is so remarkable that I think it ought to be put on record, and Sir J. H. Lefroy has kindly permitted me to make extracts from the letter for that purpose. I believe no account of the circumstances of the case has as yet been published in Europe. There seems to be no likelihood as to mistake regarding the facts. The special occurrence could probably only happen in the tropics in warm water.

H. N. MOSELEY

"In the autumn of 1878 a man committed a terrible crime in Somerset, which was for some time involved in deep mystery. His wife, a handsome and decent mulatto woman, disappeared suddenly and entirely from sight, after going home from church on Sunday, October 20. Suspicion immediately fell upon the husband, a clever young fellow of about thirty, but no trace of the missing woman was left behind, and there seemed a strong probability that the crime would remain undetected. On Sunday, however, October 27, a week after the woman had disappeared, some Somerville boatmen looking out towards the sea, as is their custom, were struck by observing in the Long Bay Channel, the surface of which was ruffled by a slight breeze, a long streak of calm such as, to use their own illustration, a cask of oil usually diffuses around it when in the water. The feverish anxiety about the missing woman suggested some strange connection between this singular calm and the mode of her disappearance. Two or three days after—why not sooner I cannot tell you—her brother and three other men went out to the spot where it was observed, and from which it had not disappeared since Sunday, and with a series of fish-hooks ranged along a long line dragged the bottom of the channel, but at first without success. Shifting the position of the boat, they dragged a little further to windward, and presently the line was caught. With water glasses the men discovered that it had caught in a skeleton which was held down by some heavy weight. They pulled on the line; something suddenly gave way, and up came the skeleton of the trunk, pelvis, and legs of a human body, from which almost every vestige of flesh had disappeared, but which, from the minute fragments remaining, and the terrible stench, had evidently not lain long in the water. The husband was a fisherman, and Long Bay Channel was a favourite fishing-ground, and he calculated, truly enough, that the fish would very soon destroy all means of identification; but it never entered into his head that as they did so their ravages, combined with the process of decomposition, would set free the matter which was to write the traces of his crime on the surface of the water. The case seems to be an exceedingly interesting one; the calm is not mentioned in any book on medical jurisprudence that I have, and the doctors seem not to have had experience of such an occurrence. A diver went down and found a stone with a rope attached, by which the body had been held down, and also portions of the scalp and of the skin of the sole of the foot, and of clothing, by means of which the body was identified. The husband was found guilty and executed."

On the Simplest Continuous Manifoldness of Two Dimensions and of Finite Extent

THERE appeared in your pages some three years ago (vol. xv. p. 515) an article of mine "On the Simplest Continuous Manifoldness of Two Dimensions and of Finite Extent." In a succeeding number a correspondent (Mr. Monro, of Barnet) propounded a query which may be shortly stated as follows:—"How does it happen that the perpendicular on a geodesic from a point moving along another geodesic changes sign without passing through either the value zero (0) or the value infinity (∞)?" The problem here suggested is a peculiarly knotty one. In the case of the Euclidian plane the perpendicular of course changes sign by passing through the value ∞, while in the case of a spherical surface it is equally obvious that the perpendicular passes through zero, since the two geodesics intersect twice. But what are we to say of the strange hybrid surface which formed the subject-matter of my paper? Your correspondent appeared to insinuate that the problem was insoluble, and that the definition of the surface must therefore involve a logical contradiction. For a while I was greatly puzzled by this unforeseen difficulty, but after a little thought came to the conclusion that the perpendicular changes sign by passing through the value $\frac{l}{2}\sqrt{-1}$, where l is positive and represents the absolute length of a complete geodesic. In other words, I conceived that the sign of the perpendicular changed from + to − by a continuous variation of the real numbers a and b in the complex number $a + b\sqrt{-1}$. I conceived a to diminish continuously till, passing through 0, it became $-a$, while b at the same time increased with simple harmonic motion from 0 to a maximum, and then decreased from a maximum to 0.

I was, however, not sufficiently clear on the matter to feel justified in addressing you until I received, the other day, a copy of a paper by Prof. Simon Newcomb, of the United States Observatory, entitled "Elementary Theorems relating to the Geometry of a Space of Three Dimensions and of Uniform Positive Curvature in the Fourth Dimension."[1] The subject-matter of this masterly paper is in reality the simplest continuous manifoldness of *three* dimensions and of finite extent. It therefore naturally includes all that had been worked out in my own paper and a little more besides. In particular it throws strong light on the difficulty raised by your correspondent. For an exactly parallel anomaly presents itself in the theory of Prof. Newcomb's solid space, and is stated in his 13th Proposition as follows:—"*The two sides of a complete plane*[2] *are not distinct, as in a Euclidian surface.*" If a being were to travel along a complete plane in a geodesic line, he would, on his return, find himself on the opposite side of the plane to that on which he started, and would have to repeat his journey in order to regain his original poise. "In this property," Prof. Newcomb says, "we find a certain amount of reason for considering the complete plane as a double surface." The corresponding anomaly in space of two dimensions—*i.e.*, the specific feature noticed as an anomaly by your correspondent—is then explained as Proposition XIV.: "The following proposition is intimately connected with the preceding one. If, moving along a right line, we erect an indefinite series of perpendiculars, each in the same Euclidian plane with the one which precedes it, then, on completing the

[1] Abdruck aus dem *Journal für die reine und angewandte Mathematik*, Bd. 83. Druck von G. Reimer in Berlin.

[2] A "complete plane" is a geodesic surface of Prof. Newcomb's space. It is in all respects identical with the surface treated of in my paper.

line and returning to our starting point, the perpendiculars will be found pointing in a direction the opposite of that with which we started." Here then is the solution of the difficulty. As we move over our surface along a geodesic, the instantaneous Euclidian plane containing the beginnings of successive perpendiculars (for *small initial* portions of two successive perpendiculars to a geodesic will lie in a Euclidian plane) rotates about the instantaneous tangent to the geodesic, and it does not complete a rotation until we have travelled *twice* the complete length of the geodesic. The perpendicular is a vector quantity, and changes sign by passing through $\frac{l}{2}\sqrt{-1}$. Also, a geodesic does not divide the surface into two completely separate regions, as a great circle does a sphere or a straight line a plane. The two regions are continuous with one another, and it is possible to get from the one to the other along a finite path without crossing the geodesic. F. W. FRANKLAND

Ascent of Etna

IT was a bright sunny sky on the last day of April when we started, with Giuseppe Sedici as guide, from the Grand Hotel at Catania in a carriage and pair bound for Nicoloni, *en route* to the summit of Etna. A dusty drive of two and a half hours, and we were at the door of the inn in the centre of the village. Its appearance was somewhat forlorn, and its fare rather meagre, but the civility of mine host compensated for all other defects. Here we engaged two mules, a porter, and a driver, an operation which took more than two hours, and then set off again for the Casa del Bosco, which we reached in the middle of the afternoon after a ride of two and a quarter hours. A climb up a neighbouring hillock to see the sunset, dinner, and a few hours' rest filled up the time till 11 p.m., when we started off again and rode for about half an hour, till the appearance of snow made it necessary to dismount and continue the remainder of the journey on foot. Our guide was very slow, and on any attempt to force the pace stood still and ejaculated: "Fermo, Signore! Piano, Piano!" so that we did not arrive at the Casa Inglese till 5 a.m., and were obliged to content ourselves with seeing the sun rise from here instead of from the top, as we had intended. It did not much matter, as it was a cloudy morning, and the view was very poor, but still it was a disappointment. The Casa Inglese was covered with snow to the eaves of the roof, the observatory buried altogether, the Val del Booe a sea of white. After a short rest we trudged on again; so far it had been good walking up an easy ascent of crisp snow, but now it became a work of difficulty to pick one's way through deep drifts and treacherous-looking holes, which seemed to explain the guide's reluctance to undertake this part of the route by moonlight. Arrived however at the foot of the cone, the snow ceased, and a heavy climb up the frozen side under a biting wind began. Half way up matters were not improved by a severe attack of sickness; but at length the top was reached at 6.20 a.m. There was no distant view; within the crater the steam and smoke kept being blown hither and thither, and cleared off at times sufficiently to show parts of what looked like a bottomless pit. It was a curious and weird sight altogether, and well repaid the fatigues of the journey. During the descent the notes of the cuckoo and some very sweet violets found by chance under the snow reminded us that, notwithstanding the mountain's wintry mantle of white, it was really spring time, and that the morning sun had ushered in the merry month of May, a fact which we had well nigh forgotten but a few hours before, when our fingers were numb with cold and our ears threatened to become a thing of the past. G.

Colour Combinations

THE production of white by red and green solutions is well seen on mixing cobalt and nickel solutions together in proper proportions. Another interesting example is that of electrically deposited copper immersed in a solution of copper sulphate. The first notice of this, so far as I know, occurs in Shaw's "Manual of Electro-Metallurgy" (1842), p. 33, in the following terms:—

"This phenomenon may be observed in great perfection by the electrotype; the solution of sulphate of copper is of an intense and pure blue; and the newly-precipitated ductile copper is of an equally pure orange; let the reader take a vessel containing the cupreous solution and place it in the sun, in order to have an abundance of light, and immerse in it, in a horizontal position, a piece of new electrotype copper; immediately the metal sinks beneath the surface of the blue solution the orange tint fades, and by placing it at a proper depth altogether vanishes, and the metallic plate appears intensely white; when nicely adjusted the plate so much resembles plaster-of-paris that a person unacquainted with the nature of the experiment would with difficulty be persuaded that it was not made of that substance."

Birmingham and Midland Institute, June 14 C. J. WOODWARD

P.S.—In mixing red and green solutions is it correct to speak of them as *producing* white? I take it that the mixture absorbs more light than the two solutions would do if separate, *i.e.*, the solution of nickel transmits a greenish white, the cobalt solution a reddish white, but together the red and green destroy each other, the excess of white light passing through. This is shown forcibly by using strong solutions, when the deep red and green produce, not white, but black.—C. J. W.

Wild Swans—Notes of Birds

THERE are at present eight wild swans in a lake not far from here. I believe them to be part of a flock of sixty which were there all through the winter. Wild swans in summer were never, so far as I know, heard of in this part of the world before. I have always carefully preserved the wild fowl on this lake, and I pay increased attention to the swans, which I hope will be safe from poachers. They swim in pairs, but show no signs of nesting.

The *major* cuckoo noticed in my letter (NATURE, vol. xxii. p. 76) is still here without any other *major* that I could find in this place or in the neighbourhood. Referring to your polite correspondent A. N., in p. 97, I must remark, for the fair fame of the cuckoos, that his theory relating to sex seems quite unsustainable. Certainly if all the minor cuckoos about here were males and the single major a female it would show an instance of polyandry (if the term can be applied to birds) such as could scarcely be matched in the whole range of natural history. I quite agree with Mr. Newton (p. 122) that the female cuckoo does not sing; and it might perhaps be unamiably suggested that the comparative silence of the females among the lower animals seems among the most marked distinctions between them and the human race.

Regarding Mr. Allen's letter (same page) I can only say that, while his experiences are so different from mine, there must be an imperfection of ear in either of us, and, without any notion of insisting on the correctness of my own, I should like, at least, to hear the testimony of other parties in the matter. Of course I referred to cuckoos in full voice in the height of the season. When their voice begins to decline, their notes vary, and, as a friend of mine expresses it, they "sing *anyhow*."

Millbrook, Tuam, June 18 J. BIRMINGHAM

Anchor-Ice

ALLOW me to say in reply to Mr. Rae's kindly criticism (NATURE, vol. xxii. p. 54) that I did not assert that the original ice-crystals *are* "at least as heavy as water," but that they "*seem*" to be so (vol. xxii. p. 81).

I have seen them collect upon stones at the bottom of waterways two or three feet in depth—where the stream though swift was smooth and unbroken,—and I have thought that this might be the result of their having a greater specific gravity than ordinary ice.

In my desire to be concise I had the misfortune to use a phrase that gave Mr. Rae the impression that I was asserting as a fact that which at best I have only regarded as possible.

Boston, June 7 C. F. C.

SCIENTIFIC RESULTS OF THE HOWGATE POLAR EXPEDITION, 1877-78

THE fifteenth *Bulletin* of the United States National Museum (Washington, 1879) consists of contributions to the Natural History of Arctic America, made in connection with the Howgate expedition in 1877-78, by Ludwig Kumlien, naturalist to the expedition, who gives

a most valuable and interesting account of his ethnological observations and important notes on the habits of the birds and mammals of the region explored. Capt. Howgate's expedition was one which had several different ends in view. The primary object of it was the collection of skins, sledges, dogs, Eskimo, and other necessaries for a future colony in Lady Franklin Bay. A secondary object was scientific exploration, whilst the only remuneration of the crew was derived from ordinary whaling operations, every one excepting the scientific men on board the *Florence* having a "lay" in the voyage. The *Florence*, in which the voyage of the expedition was made, was a fore-and-aft schooner of fifty-six tons, which had before been engaged in sealing in the southern seas. Mr. Kumlien necessarily found so small a vessel extremely disadvantageous for scientific operations. He had to leave valuable skeletons of mammalia behind, and could have procured more in addition, if only stowage room had been available.

The explorations of the expedition were made in Hogarth Sound on the western coast of Davis Straits. Hogarth Sound, the Cumberland Straits of Baffin, lies in Baffin's Land, and its western coast is called Penny's Land, after Capt. Penny, who visited it in 1839. The northern part of the Sound is crossed by the Arctic Circle. The Sound is about thirty miles wide at its widest part, its length is uncertain, but over 150 miles. It has been frequently visited by Scotch and American whalers during the last twenty-five years.

The *Bulletin* commences with a long paper by Mr. Kumlien on the Eskimo of the Sound, from which we gather the following interesting statements. The natves are fast diminishing in numbers, and the total population of the Sound is estimated by the author at not more than 400 individuals. The Eskimo are peaceful now, but have numerous traditions of former wars, in which they relate that the hurling of stones was the most effective and common mode of warfare.

The natives have, as usual, suffered by contact with white men, and the Hogarth Sound Eskimo of to-day, with his breech-loading rifle, steel knives, cotton jacket, and all the various trinkets he succeeds in procuring from the ships, is worse clad, lives poorer, and gets less to eat than did his forefathers, who had never seen or heard of a white man. He barters a seal-skin that should have been used for repairing the tent, for a little tobacco, or some valueless trinket which is soon thrown aside.

The children are, when young, quite fair; the adults are so begrimed with soot and grease, that it is impossible almost to tell their real colour, but there are some pure bred Innuits whose skins are no darker than a white man's would be if subjected to the rigours of wind and cold.

"There are at present so many whaleboats owned by the Eskimo, that they experience little difficulty in making quite extensive cruises, three or four families constituting a boat's crew. They will load a whale-boat to within an inch or two of the gunwale, and then set out for a few weeks' enjoyment and abundance. The squaws do the rowing and the captain stands majestically in the stern with the steering-oar, whilst the rest of the men are either asleep or on the look-out for game. The cargo consists of the tent-poles, the skin-tents, pots, and lamps, with sundry skin-bags containing the women's sewing and skinning utensils. The hunting-gear forms, of course, quite a conspicuous portion of the contents of the boat. Very few there are at present who have not become the possessors of half a barrel, and this vessel occupies a conspicuous place in the boat, and is constantly receiving additions of animal matter in some shape; a few young eiders or gulls will soon be covered up with the intestines of a seal and its flesh. From this receptacle all obtain a piece of meat whenever they feel hungry. This vessel is never emptied of its contents except by accident or when scarcity of material forbids its repletion; and as the temperature at this season is well up in the sixties during the day, this garbage heap becomes so offensive as to be unbearable to any but an Eskimo."

The powers of endurance of these Eskimo appear to be no better than those of whites. Few of them could stand a tramp through the snow all day long better than the members of the expedition, but, as in the case of other savages, it was in "tracking" that they showed their superiority most markedly. "They will follow animal tracks in the snow for a whole day when we confess we could not discover the faintest trace of a track except at long distances apart."

The women's dress differs from that of the men in that their trousers are composed of three separate pieces, the lower reaching from a little below the knee to the middle of the thigh; when at work in their igloos they take off the lower pieces and use their bare thighs as boards for cleaning sealskins on. Amongst most races, as in England, the dress of young children—both boys and girls—resembles that of their mothers, but Eskimo little girls wear trousers like those of the men, made all in one piece, until they are twelve years old.

Most of the Eskimo cannot count higher than ten, and many not higher than six; some are said to have numbers to twenty, but they are few. The names of the same numerals are differently pronounced, and difficulty was experienced in finding a native who knew the names well enough to give them all up to ten.

When a woman is about to be confined she is placed in a small skin tent in summer or a small snow hut in winter, with a little girl only to attend her. This is done for fear the mother or child may die, in which case the tent and all in it could never be used again. For the same reason any native when very ill is carried out to die. In some instances this custom is obliged to be modified. For example, a tent cover thus under tabu is sometimes cut off at about two feet from the ground all round, and the top is used. In one case a man's wife shot herself accidentally in her igloo; the gun was too great a sacrifice for the husband; he used it, but everything else was left to waste away where it lay. After the birth of the child the mother, with the child on her back, is conducted by an aged female ancoot to a level spot on the ice, where a curious ceremony of marching in circles is performed.

The following legend gives directions as to how a person may become an *ancoot* or *angekok*. It is interesting because it does not differ essentially from the Greenlanders' account of the same thing. An "ancoot" may be regarded as the most primitive representative of the priestly office.

"Any one wishing to be an ancoot must go away a long distance from where there is any other person. Then he must find a large stone and seat himself by it, and call on *Torngarsuk* (the greatest spirit of good and evil; the name is now used by instructed natives for the devil). This spirit will then make himself present to him. The would-be ancoot will at first be very much frightened at the arrival and appearance of the spirit, so much so that he is seized with severe pains and falls down and dies, and remains dead for three days. Then he comes to life again, and returns home a very wise man."

An ancoot's duty is, first, to heal the sick by muttering over them; secondly, to talk to Torngarsuk and get useful information; thirdly, by this means to foretell deaths and misfortunes. He leads in such ceremonies as the killing of the evil spirit of the deer, an extraordinary jumping, shouting, and stabbing performance directed against an imaginary deer. A successful ancoot of long standing may reach higher grade and become a great ancoot by means of periods of fasting and an existence for a time in the condition of a walrus.

If an ancoot's prophecy does not come to pass, he says that a halo, corona, aurora, or some such phenome-

non which has occurred has broken the spell; but often he is truly oracular in his utterances, as in a case overheard by the author, in which one was asked by a young woman if her child would be a boy or a girl. He went outside the hut for a time, and on returning said it would "be a boy," but "if it is not a boy it will be a girl." His fee for this was three sealskins and a knife.

The Hogarth Sound Eskimo, unlike the Greenlanders, have no permanent habitations. They live in snow houses (*igloos*) till June, when the snow melts, and then take to their skin tents or *toopiks* till the latter part of October, when they build igloos again.

A detailed account of the mode of making of the igloos is given, and a horrible one of the condition of the inhabited interior. Behind and around the lamps the Eskimo pile up their meat, and the pile soon becomes extremely offensive both to sight and smell. Meat is sometimes brought in that is already spoiled, although the temperature may be 50° below zero. This often happens with deer, which, unless disembowelled as soon as killed, rapidly decompose inside before freezing through.

Bows and arrows have been discarded for fire-arms, but are, as usual amongst other races, maintained in use by the children, who kill snow-birds and lemmings with them. The Eskimo are not very expert at making traps or snares apparently, but the simple box-trap of ice for foxes seems to be very effective. The slab of ice which falls and closes it is simply supported by a small upright of ice resting on the bait, and comes down directly the fox pulls at the meat. The author tried steel traps for the foxes, without success; the wily foxes always dug under the traps in the snow, and got at the bait from below.

Nearly all the Eskimo become snow-blind in spring, and generally do not put on their well-known wooden eye-blinkers until the condition of their eyes forbids their going out without them.

The ceremony of greeting a stranger on his arrival at a village is curious, and ends by the ancoot and the stranger stepping out before the villagers and dealing one another alternately a knock-down blow on the cheek, the ancoot of course having first hit: the two then kiss. In another ceremony vestments are used, that is to say, the ancoot puts on a great many pairs of trousers, as a preparation. Formerly all the implements of a dead man were left to rot in his grave, as amongst other American races and so very many peoples in various parts of the world, but of late years the Eskimo have amended this usage, and after the things have remained a short time in the grave, they are taken out and used again by the relatives. In very recent graves tin cups and pots, knives, and even one fork, a photograph, and a *Harper's Weekly Newspaper* were found, a fact which reminds us of having seen a sewing machine rusting on the grave of a Chinook woman in Oregon.

Charms of very various kinds are worn about the person by the Eskimo, and much prized and handed down for generations; one such consisted of two small stones, one a bluish flint, the other apparently meteoric iron. An ancestor discovered by accident that the two would strike fire, and became, in consequence of their possession, a great man amongst the people. The old woman to whom this charm belonged, considered it of inestimable value, for she said, "No one has yet died while wearing this charm." The ancoots are often very expert jugglers. A common trick is for one of them to come into a hut with a harpoon toggled in his breast and the handle sticking in his back, the wound bleeding profusely.

Of the creation of man the Eskimo say: "In the beginning there grew up from the earth a man; he got a wife from one of his *thumbs*, and from this pair the race has originated. But the whites, whom they call *cablunet*, or *codlunak*, they have sprung from dogs. An Eskimo woman at one time gave birth to human beings and dogs. The latter she put in an old boot, and threw them out into the sea, saying, Go hence, and become white people. From this it happens that the whites live on the sea and their ships are like Innuit's boots, round at both ends. This is a very different notion from the Australian "tumble down, black fellow, jump up, white fellow," and less complimentary to the pale faces.

A good deal of the information about the Eskimo given by the author is of course not new, but the descriptions are very fresh and good, and it is of importance to have so full an account of the present condition of the natives of the west coast of Davis Straits.

An account of the mammalia of Hogarth Sound by the same author follows the ethnological ones. The mammalia seem to be disappearing from the neighbourhood with great rapidity. Bears, walrus, and the hooded seal are very scarce up the sound, and of the musk-ox the traces remain only in the personal name "omingmuk," which is used commonly amongst the Eskimo, who know the animal well as found far to the north.

In the account of the Eskimo dogs the curious theory is upheld by Mr. Kumlien that the peculiar rabies of which they so commonly die is produced in the males by unrequited affection towards the opposite sex, and instances in proof are cited. At least four-fifths of the dogs so dying are males.

There is an interesting account of the various seals of the coast and their habits, and of the modes of catching them adopted by the Eskimo, and also of the whales. The author has known the white whales (*Beluga catodon*) to come in close proximity to the ship and lie along her sides for protection when pursued by the grampus or killer, *Orca gladiator*. The white whales ascend the sound as soon as the ice begins to loosen, but for what purpose seems uncertain; the mothers already have their young with them, and as little or nothing is found in the animals' stomachs when killed, they do not appear to go up the sound for food. In July they repair in hundreds to the sand-beaches of the fjords. The author suggests that perhaps they roll against the sand to free themselves of parasites. Numerous seals (apparently *Pagomys fœtidus*) were found inhabiting a fresh-water lake, Lake Kennedy, lying at a considerable distance inland.

In the account of the birds, also by Mr. Kumlien, some curious notes on the habits of ravens, which are extraordinarily common on the sound, are given. Six or seven hunting in company soon kill a young reindeer, and "in the capture of the young seal, *Pagomys fœtidus*, the birds evince a considerable degree of intelligence. I have on different occasions witnessed them capture a young seal that lay basking in the sun on the ice near its hole. The first manœuvre of the ravens was to sail leisurely over the seal, gradually lowering with each circle, till at last one of them suddenly dropped directly into the seal's hole, thus cutting off its retreat from the water. Its mate would then attack the seal, and endeavour to drag or drive it as far away from the hole as possible. The attacking raven seemed to strike the seal on the top of the head with its powerful beak, and thus break the tender skull. In two instances I allowed the combat to proceed until the seal was killed, and then drove the ravens away. I found no marks upon the seal except those of the blows upon the head, which had fractured the skull in two places." Two ravens were seen to chase a hare in concert and kill it.

We regret that we cannot follow the author further.

The *Bulletin* contains lists of the fishes collected in addition, by Mr. T. H. Bean, with descriptions of species; of the crustacea by Mr. S. S. Smith; of the annelides, tunicata, bryozoa, echinoderms, and cœlenterates by Prof. Verrill; of the mollusca by Mr. W. H. Dall; of the insects by Messrs. Edwards and Scudder; and of the plants by Prof. Asa Gray and Messrs. E. Tuckerman and W. G. Farlow.

EXPERIMENTAL RESEARCHES IN ELECTRICITY[1]

II.

THE experiments were made in a bell-jar, containing the terminals, which could be gradually exhausted after having been filled with air or other gas. One of the terminals was fixed to the bottom plate, the other could be adjusted to any distance from it by a rod sliding through a stuffing-box in the glass cover. The foot of the stand was insulated by a disk of ebonite, on which it stands. One such bell-jar is 9¼ inches (23·4 centims.) high, and 5⅞ inches (14·9 centims.) in diameter; its cubical content, ascertained by covering the open ends with glass plates and filling with water from a graduated measure, was found to be 3,787 cub. centims.

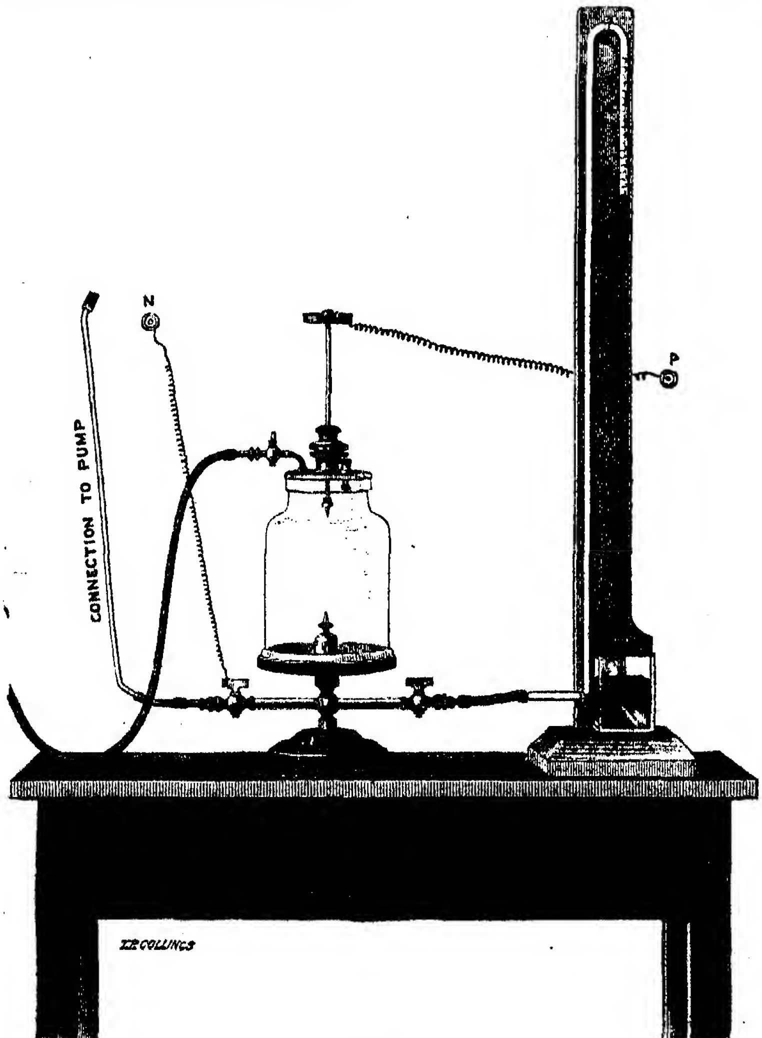

FIG. 3.

A remarkable phenomenon was observed on making connection between the terminals and the battery by means of the discharging key, namely, that within certain limits of pressure in the bell-jar a sudden expansion of the gas took place, and that as soon as the connection was broken the gas then as suddenly returned nearly, but not quite, to its original volume in consequence of a slight increase of temperature. The effect was exactly like that which would have been produced if an empty bladder had been suspended between the terminals and suddenly inflated and as suddenly emptied.[1]

The following experiment in rarefied air, at a pressure of 56 mm., at a temperature of 17°·5 C., will give an idea of the amount of instantaneous expansion which occurs when the terminals are connected with the poles of the battery of 11,000 cells, current 0·01102 W; the resistance of the bell-jar was reproduced by substituting 600,000 ohms wire resistance.

	mm.	M.
Distance of the terminals—the top one a point, the lower a disk—6 in.; pressure	56	73,684
On making contact the arc passed and the column of mercury was depressed ...	15·8	20,789
Pressure on connection ...	71·8	= 94,473

The increased was to the normal pressure in the ratio of 1·282 to 1; as the gas was kept at a constant volume, and supposing the expansion to be due to an increase of temperature, the pressure would vary as the absolute temperature,[2] therefore

$$\frac{T'}{T} = \frac{71\cdot8}{56} = 1\cdot282, \text{ whence}$$

$$T' = 1\cdot282 \times 291\cdot2 = 373^{\circ}\cdot3 \text{ C.};$$

$$(373\cdot3 - 273\cdot7) = 99^{\circ}\cdot6 \text{ C.},$$

the temperature of the bell-jar, and $(99\cdot6 - 17\cdot5) = 82^{\circ}\cdot1$, the rise of temperature while the discharge was taking place. But the temperature of the bell-jar as determined by a thermometer inclosed in it with its bulb uppermost only rose 0°·64 C. per second, taking into account the rate of cooling. It is evident, therefore, that the increase of pressure cannot be ascribed to the instantaneous heating of the bell-jar 82° C.

Taking the dimensions of the arc from a photograph shown in the plate, Fig. 30, it was calculated that it must have attained the enormous temperature of 16,114° C., if the increase of pressure was really due to heat. It was found that platinum wires 0·001 inch in diameter supported in various parts of the arc, as shown in the plate, Fig. 30, were immediately fused; the temperature of the arc was therefore as high as the fusion-point of platinum, and possibly considerably higher.

If the whole of the heat evolved by a current of 0·01102 W, through a resistance of 600,000 ohms had been communicated to the air in the jar, weighing 0·339 grm., it would raise it 215°·6 C. in one second. It is known from direct experiment that this enormous evolution of heat was not communicated to any extent to the air in the bell-jar, because its temperature only increased about 0°·64 C. per second; the heat must consequently have escaped almost instantaneously by radiation. It is difficult consequently to realise the conjecture that the enormous dilatation which occurred instantaneously could have been caused by increase of temperature. And it points to its being produced by a projection or scattering of the molecules by electrification causing them to press outwards against the walls of the containing vessel, this pressure being distinct from the motion caused by heat.

[1] "Experimental Researches on the Electric Discharge with the Chloride of Silver Battery," by Warren De La Rue, M.A., D.C.L., F.R.S., and Hugo W. Müller, Ph.D., F.R.S. Continued from p. 153.

[1] De la Rive noticed that oscillations occurred in the mercury of a gauge attached to an exhausted tube as soon as the current passed.

[2] Absolute zero = 273·7 C., 273·7 + 17·5 = 291·2

The authors proceed to describe the appearance of the arc with terminals of various forms at different distances and with various pressures. It was found that the light emitted by different parts of the arc was not of the same intensity throughout, and that from the first there was a tendency to break up into distinct entities, as shown at A, B, C, D, E, F in the diagram, Fig. 4, which only indi-

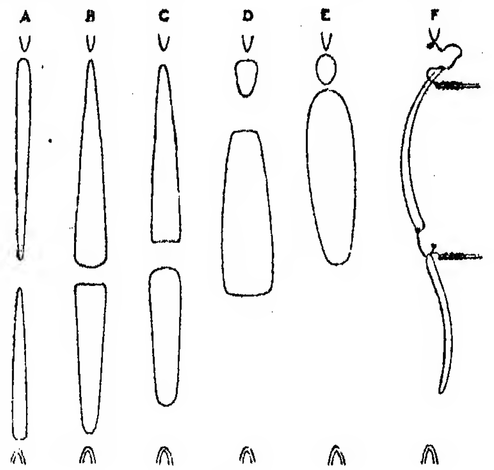

Fig. 4.

cates the central bright portion of the arc, this never quite reached the negative terminal, near which there was always the well-known dark discharge.

As the pressure was diminished the arc widened out, until at last the entire surface of the negative disk was covered with a luminous halo, and the discharge took up a stratified appearance.

The appearances presented by the arc in air, hydrogen, and carbonic acid are illustrated by copies of photographs and drawings in mezzotint, as shown in the Plate.

The arc in air between two points at various distances and pressures with a constant number of cells. Temp. 12·7 C. The references are to the Plate

11,000 cells, distance 0·54 inch, pressure atmospheric, current 0·02456 **W**; the total resistance of battery and arc was found to be 461,500 ohms, that of the arc, by substituting wire resistance, 27,550; whence the potential between the terminals was 657 cells. The appearance of the arc is shown in the plate, Fig. 20; it exhibits clearly the tendency to break up into luminous entities; the photograph of which this is a copy is nearly full size, and was obtained in twenty seconds. All the other copies of photographs are on a reduced scale. As the batteries were undergoing the annual overhauling, the number of cells, some being removed from time to time, was somewhat less in the following experiments, namely, 10,940.

Fig. 1, from a photograph obtained in 10 seconds.—Pressure atmospheric 748·6 mm., 985,000 **M**, distance 0·58 inch, current not observed, no depression of the mercury in the gauge was noticed; indeed, it will be seen that at the higher pressures the depression is generally less than at the lower, up to a certain point.

Fig. 2, from a photograph in 15 seconds.—Distance 0·58 × 2 = 1·16 inch, pressure 294·9 mm., 388,026 **M**, current 0·02881 **W**, depression 16 mm., total pressure 294·9 + 16 = 310·9; ratio of increased to normal pressure as 1·054 to 1. It will be observed that the central spindle has become bifurcated about midway.

Fig. 3, from a photograph in 15 seconds.—Distance × 3 = 1·74 inch, pressure 191·3 mm., 251,711 **M**, current 0·04060 **W**, depression 17 mm., total pressure 208·3 mm.; ratio of increased pressure 1·089. The bifurcation is apparent in this also.

Fig. 4, in which the central spindle is broken up into several luminosities.—Distance × 4 = 2·32 inches, pressure 142·6 mm., 187,631 **M**, current 0·04474 **W**, depression 19 mm., total pressure 161·6 mm.; ratio of increased pressure 1·133.

Fig. 5, from a photograph in 15 seconds; in this the central spindle is split up into bright entities connected by less bright portions.—Distance × 5 = 2·9 inches, pressure 112·6 mm. 148,157 **M**, current 0·03459 **W**, depression 19 mm., total pressure 131·6; ratio of increased pressure 1·169.

Fig. 6, from a photograph in 15 seconds. The luminous entities still seen, but are less marked.—Distance × 6 = 3·48 inches, pressure 99·4 mm., 130,789 **M**, current 0·03071 **W**, depression 21 mm., total pressure 120·4 mm.; ratio of increased pressure 1·211.

Fig. 7, from a photograph in 15 seconds.—Distance × 7 = 4·06 inches, pressure 85·9 mm., 113,026 **M**, current 0·03259 **W**, depression 22 mm., total pressure 107·9 mm.; ratio of increased pressure 1·256. The central spindle is divided into two luminosities, with a tendency to form a third near the negative.

Fig. 8, from a photograph in 15 seconds.—Distance × 8 = 4·64 inches, pressure 71·6 mm., 94,210 **M**, current 0·02693 **W**, depression 22 mm., total pressure 93·6 mm.; ratio of increased pressure 1·307. The central spindle nearly of the same character as Fig 7.

Fig. 9, from a photograph in 15 seconds.—Distance × 9 = 5·22 inches, pressure 65·5 mm., 86,184 **M**, current 0·02693 **W**, depression 22 mm., total pressure 87·5 mm.; ratio of increased pressure 1·336. The bright entities show a tendency to break up into less bright portions.

Fig. 10, from a photograph in 15 seconds.—Distance × 10 = 5·8 inches, pressure 64·4 mm., 84,737 **M**, current 0·03071 **W**, depression 20 mm., total pressure 84·4 mm.; ratio of increased pressure 1·310. The arc resembles that seen in Fig. 9.

The appearance of the arc between disks in hydrogen at the various pressures used in determining the potential necessary to produce a discharge, is represented in the plate, Figs. 11-19.

The arc in hydrogen between two points. Temp. 16°·2 C., 10,940 *cells*

Distance 0·75 inch, pressure 745 mm., 980,263 **M**, current 0·01575 **W**, the appearance is represented in the plate, Figs. 21 and 22, the first copied from a photograph obtained in 5 seconds, the second in 15 seconds. The central spindle breaks into a brush-like form towards the negative, there is then a dark interval between it and the glow on the negative.

Fig. 26, from a drawing.—Distance 0·9 inch, pressure 745 mm., 980,263 **M**, the discharge passed intermittently, so that the current could not be read off on the galvanometer. The appearance is represented full size.

Figs. 23, 27, 28.—Distance 0·9 × 2, 1·8 inch, pressure 385·6 mm., 507,368 **M**, current 0·01575 **W**, depression 14 mm., total pressure 399·6 mm., ratio of increased pressure 1·04. Fig. 23 is from a photograph in 13 seconds. The distance between the brush-like termination of the central spindle and the glow on the negative has relatively increased. Figs. 27 and 28 are other representations copied from drawings.

Fig. 24, from a photograph in 15 seconds.—Distance × 3, 2·7 inches, pressure 317·8 mm, 418,158 **M**, current 0·00580 **W**, depression 13 mm., total pressure 330·8 mm.,

ratio of increased pressure 1·04. The central spindle relatively still shorter. At times only the terminals were illuminated, but sometimes strata formed on the positive terminal. Fig. 29 is another representation copied from a drawing.

Fig. 25.—Distance × 4, 3·6 inches, pressure 170·5 mm., 224,342 M, 6300 cells, current not measured. The central spindle has decreased relatively still more.

Fig. 34, Distance × 7, 6·3 inches, pressure 3 mm., 3947 M, 1200 cells, the bottom point positive current 0·03896 W, a splendid stratification, though somewhat unsteady; the figure partly copied from a photograph, partly from drawings. It was thought at first that well-defined strata would not be formed in a jar of such large diameter with the quantity of current at disposal, but this experiment shows that this conjecture was unfounded. The negative glow completely fills the neck of the jar.

Fig. 31.—Distance 6·3 inches, pressure 2·4 mm., 3158 M, 1200 cells, current 0·02728 W, a very steady stratification when the bottom point was positive; this curious stratification completely overlapped the whole surface of the bottom point and the brass holder, as if pushed back by a force emanating from the negative, the glow around the negative completely filled the upper portion of the jar.

An inner tube was now inserted in the bell-jar in order to ascertain whether the contraction of the space surrounding the discharge would have any effect on the production of strata. A number of holes had been drilled in opposite sides of the tube, which is 8 inches long and 1·8 inch in diameter. These holes were drilled with the object of straining very fine platinum wires across at different heights for ascertaining the temperature of the arc at these positions, but in the experiments about to be described there were no wires.

The bell-jar was refilled with hydrogen and exhausted; distance of points 6·3 inches, pressure 2 mm., 2,632 M, 2,400 cells; when the top point was positive there was a production of ordinary strata resembling (Fig. 32). But when the bottom was positive a very remarkable phenomenon was observed, namely, the protrusion of strata through the small holes, $\frac{1}{8}$th *inch in* diameter, in the walls of the inner tube, this being accompanied by an *overpouring* of negative discharge above the top of it (Fig. 33). It seemed as if the positive discharge sought a complete neutralisation with negative electricity beyond the confines of the tube, the area of which was too small to permit of complete relief. The close confinement of the discharge at the bottom end of the tube which rests *on the glass plate of the pump may account for the non-oozing* out of strata through the holes when the top point was positive.

Some gas let in, pressure 4 mm., 5,263 M, 2,400 cells, current 0·15470 W, a well-defined stratification occurred when the bottom point was negative, but no oozing out through the holes in the tube, Fig. 32.

In order to prosecute their experiments in a vessel of still greater capacity, the authors had constructed a larger jar with a neck at each end, or more properly speaking, perhaps, a tube supported horizontally on ebonite crutches. It is 37 inches long and $5\frac{13}{16}$ inches in diameter, its cubical content was found to be 14,435 cub. centims., or 3·8 times that of the bell-jar employed in the experiments on the electric arc. The tube is shown in Fig. 5.

The experiments with this tube will necessarily occupy a considerable period, partly on account of the long time it takes to exhaust it after each set, partly on account of the variety of experiments it is intended to make with it; consequently they describe only a few of the first results hitherto obtained.

For Example in Air.

Pressure 3 mm., 3,947 M, 6,300 cells. Two luminosities were formed, the ring negative being surrounded with a nebulosity which completely filled the end of the tube. The tube glowed brilliantly with a blue fluorescent light, which proved to have great actinic power. A dry-plate photograph obtained in five seconds records a very curious phenomenon, namely, that the outer boundary of the

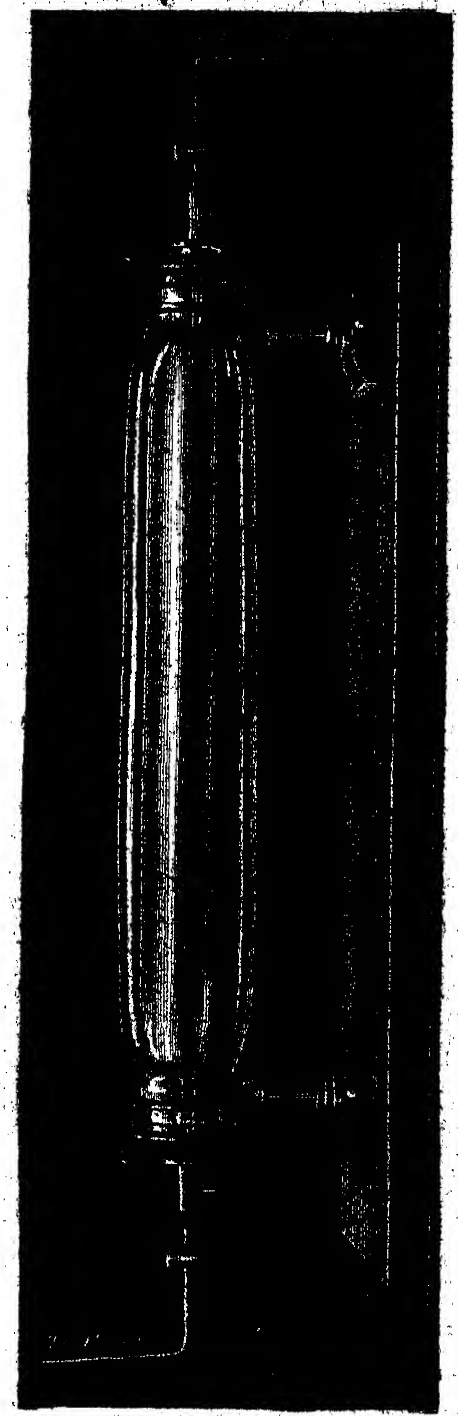

Fig. 5.

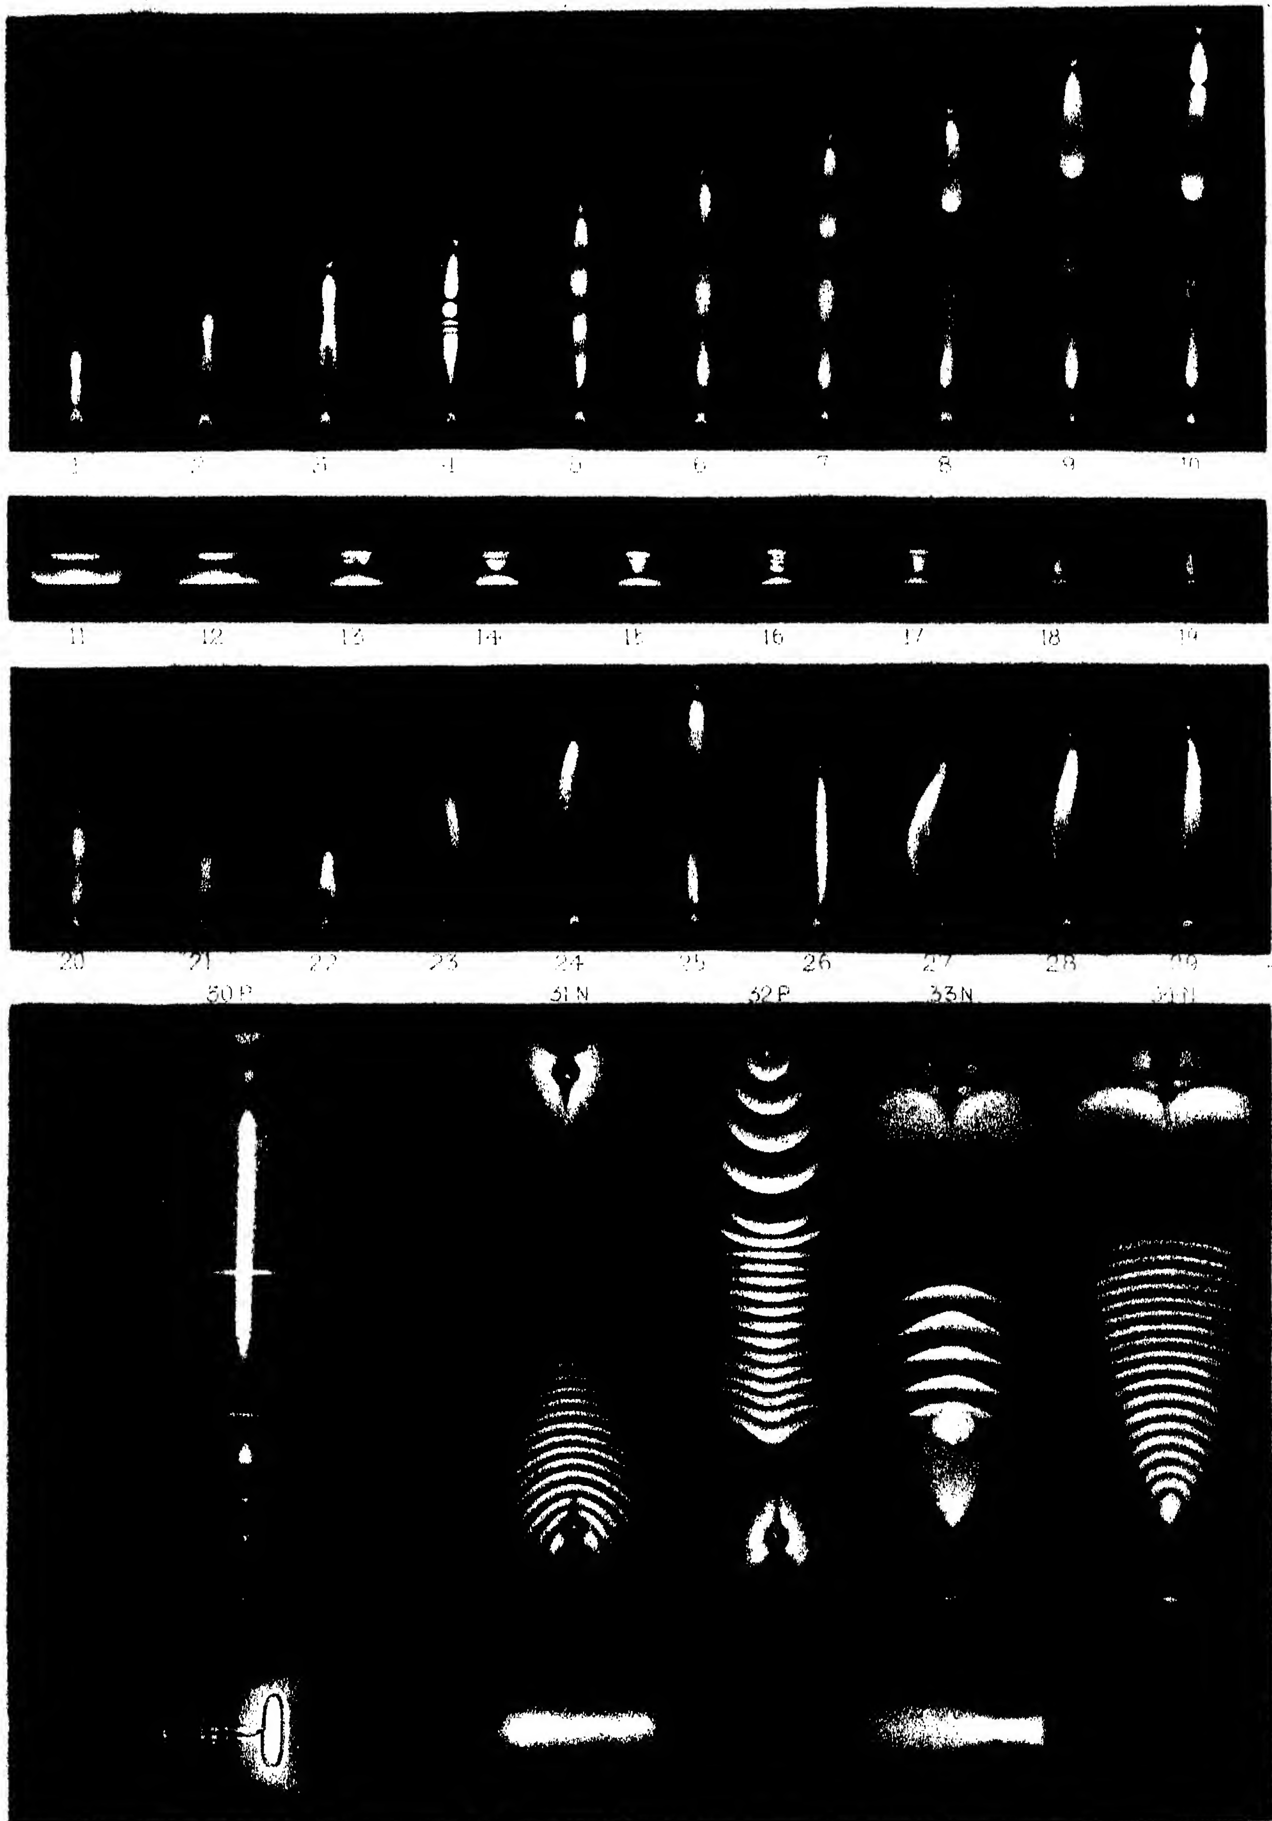
luminosity appears *darker* than the tube (Fig. 35). It is to be remarked that while the discharge was reddish (nitrogen), the fluorescence of the tube was blue; the effect appears to be due to the absorption of a portion of the fluorescent light emanating from the back of the



D. J. Pound Sculpt.

tube in passing through the red luminosity. The effect was quite unexpected, and it was thought at first that it might have arisen from some peculiarity in the development of the dry plate; it was not therefore until the result had been confirmed by other photographs that they ventured on the explanation above given.

A few experiments were made with hydrogen in this same tube; and the appearances observed are shown in Fig. 6, A B C.

Pressure 22 mm., 28,948 M, 11,000 cells, current 0·01412 W. The glow on negative extended to three-eighths of an inch, a spear-head luminosity on the positive wire, to which it was attached by a very bright wire-like stem not greater in diameter than the terminal, A (Fig. 6).

Pressure 15 mm., 19,737 M, 11,000 cells, current 0·03071 W. A spindle-shaped luminosity at the positive about 1¼ inch long, and the negative ring completely surrounded with a glow which had increased considerably since A. After a short time the spindle on the positive lengthened out and nearly reached the negative, hugging the under-side of the tube as in B (Fig. 6). It was not sensitive to the approach of the finger, although close to the glass; 6,300 cells produced the same phenomena.

Pressure 4 mm., 5,263 M, 6,300 cells, current 0·0345 W. The discharge in the latter case was partially stratified, C.

The paper closes with the following conclusions:—

1. *For all gases there is a minimum pressure which offers the least resistance to the passage of an electric discharge. After the minimum has been reached, the resistance to a discharge rapidly increases as the pressure of the medium decreases.* With hydrogen the minimum is 0·64 mm., 842 M; at 0·002 mm., 3 M, it is as great as at 35 mm., 46,000 M.

2. *There is neither condensation nor dilatation of a gaseous medium in contiguity with charged terminals.*

3. *When the discharge takes place there is a sudden*

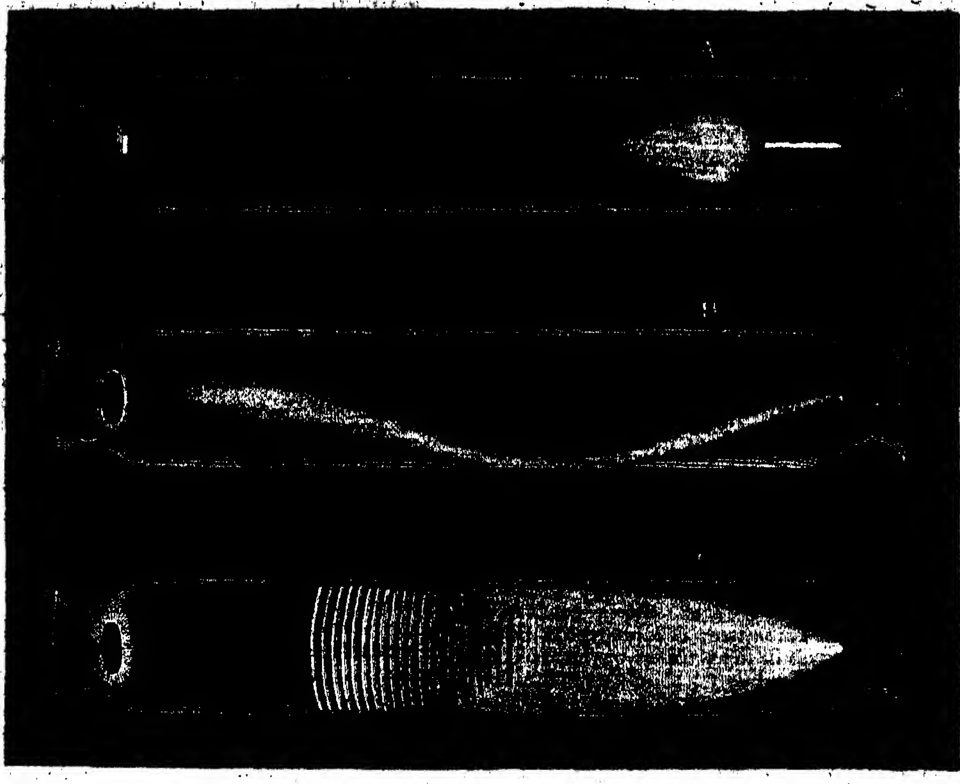


Fig. 6.

dilatation of the medium in addition to, and distinct from, that caused by heat. This dilatation ceases instantaneously when the discharge ceases.

4. *The potential necessary to produce a discharge between parallel flat surfaces at a constant distance and various pressures, or at a constant pressure and various distances, may be represented by hyperbolic curves. The resistance of the discharge between parallel flat surfaces being as the number of molecules intervening between them.*

5. *This law does not hold with regard to points. In Part I. it has been shown that the potential necessary to produce a discharge at the atmospheric pressure and various distances is as the square root of the distances, while with a constant potential and various distances, the pressure has to be diminished in a greater ratio than that of the increase of distance in order to permit a discharge to take place.*

6. *The electric arc and the stratified discharge in vacuum tubes are modifications of the same phenomenon.*

Lastly, the authors say:—

"We have again pleasure in thanking Prof. Stokes for his much-valued advice during the course of our investigations. To our assistant, Mr. Fram, we are indebted for his able co-operation; and we have to thank Mr. H. Reynolds for his aid and skill in taking photographs."

THE NEW FRESHWATER JELLY FISH

WE have received the following communications on this subject:—

The Freshwater Medusa

WHEN I last week sent you an account of the new genus of freshwater Medusæ, to which I gave the name Craspedacustes, I was not aware that Prof. Allman had prepared, or even that he was intending to prepare, an account of the same animal for the Linnean Society's

meeting of Thursday (your day of publication). The specimens on which I worked were given to me by Mr. Sowerby, the secretary of the Botanical Society, who discovered the animal, and in reply to my particular inquiry as to whether any naturalist had been charged by him with the task of working it out, he said that no one had, but that he had freely given specimens to several gentlemen. He asked me to find a name for the new Medusa, and I promised to send him a copy of what I should publish on the subject.

I hold it to be a very excellent thing that there is a certain kind of honour attaching to the priority of description of new and important genera among zoologists. It appears to me to give a zest and stimulus to hard work in the cause of zoology which is very far from being a thing to be despised. I confess to having worked at that Medusa day and night when I first obtained it, with the object of having the pleasure and honour of being the first to expound its structure to my brother naturalists.

At the same time I wish to say that had I known that so esteemed and veteran a zoologist as Dr. Allman was anxious to associate himself with this little novelty, I should have felt it to be only consistent with the great personal regard which I entertain for him to abstain from any publication on the subject until he had come forward to provide the new Medusa with a name, which I am sure would have been a prettier one than my somewhat unwieldy proposal.

Under these circumstances it gives me great pleasure to say that, so far as I am concerned, I am quite willing to give up the name Craspedacustes, and to adopt Prof. Allman's name for the new freshwater Medusa whenever he may publish it.

I have no doubt that we shall shortly hear a great deal more about the freshwater Medusa, since it is very abundant in the Regent's Park lily-house, and since Mr. Sowerby, with true scientific liberality and courtesy, freely allows naturalists who desire specimens to provide themselves with such, and has very properly placed no restriction upon their study or on the publication of results.

E. RAY LANKESTER

On "*Limnocodium victoria*," a Hydroid Medusa of Fresh Water

A SHORT time since I received from Mr. Sowerby, Secretary of the Royal Botanical Society, a letter informing me of the occurrence of certain Medusoid organisms in the warm-water tank devoted to the cultivation of the *Victoria regia* in the Gardens of the Society. The letter contained a request that I should examine the animals with a view to their determination; Mr. Sowerby accompanied it with rough sketches, and offered to place specimens at my disposal for investigation.

The discovery of true freshwater Medusæ was so startling a fact that I lost no time in calling on Mr. Sowerby, with whom I visited the tank, and carried away such specimens as were needed for examination.

The water in the tank had then a temperature of 86° F., and was literally swarming with little Medusæ, the largest of which measured nearly half an inch in transverse diameter. They were very energetic in their movements, swimming with the characteristic systole and diastole of their umbrella, and apparently in the very conditions which contributed most completely to their well-being.

As it now became evident that the Medusa belonged to a generic form hitherto undescribed, I prepared for the Linnean Society a paper containing the results of my examination, and assigning to the new Medusa the name of *Limnocodium victoria* (λίμνη, a pond, and κώδων, a bell). This was received and recorded by the secretaries on June 14, and read at the next meeting, on the 17th.[1]

[1] Some facts in addition to those contained in my original paper are included in the present communication.

The umbrella varies much in form with its state of contraction, passing from a somewhat conical shape with depressed summit through figures more or less hemispherical to that of a shallow cup or even of a nearly flat disk. Its outer surface is covered by an epithelium composed of flattened hexagonal cells with distinct and brilliant nucleus. The manubrium is large; it commences with a quadrate base, and when extended projects beyond the margin of the umbrella. The mouth is destitute of tentacles, but is divided into four lips, which are everted and plicated. The endoderm of the manubrium is thrown into four strongly-marked longitudinal plicated ridges.

The radial canals are four in number; they originate each in an angle of the quadrate base of the manubrium, and open distally into a wide circular canal. Each radial canal is accompanied by longitudinal muscular fibres, which spread out on each side at the junction of the radial with the circular canal.

The velum is of moderate width, and the extreme margin of the umbrella is thickened and festooned, and loaded with brownish-yellow pigment cells.

The attachment of the tentacles is peculiar. Instead of being free continuations of the umbrella margin, they are given off from the outer surface of the umbrella at points a little above the margin. From each of these points, however, a ridge may be traced centrifugally as far as the thickened umbrella margin; this is caused by the proximate portion of the tentacle being here adnate to the outer surface of the umbrella. It holds exactly the position of the "mantelspangen" or *peronia*, so well developed in the whole of the Narcomedusæ of Haeckel, and occurring also in some genera of his Trachomedusæ. Its structure, however, differs from that of the true *peronia*, which are merely lines of thread-cells marking the path travelled over by the tentacle as the insertion of this moved in the course of metamorphosis from the margin of the umbrella to a point at some distance above it, while in Limnocodium the ridges are direct continuations of the tentacles whose structure they retain. They become narrower as they approach the margin.

The number of the tentacles is very large in adult specimens. The four tentacles which correspond to the directions of the four radial canals or the perradial tentacles are the longest and thickest. The quadrant which intervenes between every two of these carries, at nearly the same height above the margin, about thirteen shorter and thinner tentacles, while between every two of these three to five much smaller tentacles are given off from points nearer to the margin, and at two or three levels, but without any absolute regularity; indeed, in the older examples all regularity, except in the primary or perradial tentacles, seems lost, and the law of their sequence ceases to be apparent.

I could find no indication of a cavity in the tentacles; but they do not present the peculiar cylindrical chorda-like endodermal axis formed by a series of large, clear, thick-walled cells which is so characteristic of the solid tentacles in the Trachomedusæ and Narcomedusæ. From the solid tentacles of these orders they differ also in their great extensibility, the four perradial tentacles admitting of extension in the form of long, greatly-attenuated filaments to many times the height of the vertical axis of the umbrella, even when this height is at its maximum; and being again capable of assuming by contraction the form of short thick clubs. Indeed, instead of presenting the comparatively rigid and imperfectly contractile character which prevails among the Trachomedusæ and the Narcomedusæ, they possess as great a power of extension and contraction as may be found in the tentacles of many Leptomedusæ (Thaumantidæ, &c.). These four perradiate tentacles contract independently of the others, and seem to form a different system. All the tentacles are armed along their

length with minute thread cells, which are set in close somewhat spirally-arranged warts.

The lithocysts or marginal vesicles are, in adult specimens, about 128 in number. They are situated near the umbrellar margin of the velum, between the bases of the tentacles, and are grouped somewhat irregularly, so that their number has no close relation with that of the tentacles. They consist of a highly refringent spherical body, on which may be usually seen one or more small nucleus-like corpuscles, the whole surrounded by a delicate transparent and structureless capsule. This capsule is very remarkable, for instead of presenting the usual spherical form, it is of an elongated piriform shape. In its larger end is lodged the spherical refringent body, and it thence becomes attenuated, forming a long tubular tail-like extension which is continued into the velum, in which it runs transversely towards its free margin, and there, after usually becoming more or less convoluted, terminates in a blind extremity.

The marginal nerve-ring can be traced running round the whole margin of the umbrella, and in close relation with the otolitic cells. Ocelli are not present.

The generative sacs are borne on the radiating canals, into which they open at a short distance beyond the exit of these from the base of the manubrium. They are of an oval form, and from their point of attachment to the radial canal hang down free into the cavity of the umbrella. Some of the specimens examined contained nearly mature ova, which, under compression, were forced from the sac through the radial canal into the cavity of the stomach.

While some of the characters described above point to an affinity with both the Trachomedusæ and Narcomedusæ, this affinity ceases to show itself in the very important morphological element afforded by the marginal bodies. In both Trachomedusæ and Narcomedusæ the marginal bodies belong to the tentacular system; they are metamorphosed tentacles, and their otolite cells are endodermal, while in the Leptomedusæ, the only other order of craspedotal Medusæ in which marginal vesicles occur, these bodies are genetically derived from the velum. Now in Limnocodium the marginal vesicles seem to be as truly velar as in the Leptomedusæ. They occur on the lower or abumbral side of the velum, close to its insertion into the umbrella, and the tubular extension of their capsule runs along this side to the free margin of the velum, while the delicate epithelium of the abumbral side passes over them as in the Leptomedusæ. It is true that this point cannot be regarded as settled until an opportunity of tracing the development is afforded; but in very young specimens which I examined I found nothing opposed to the view that the marginal vesicles were derived, like those of the Leptomedusæ, from the velum.

Important points still remain to be cleared up regarding the development of Limnocodium and the determination of the question whether the Medusa be derived from the egg directly or only through the intervention of a hydranlid trophosome. I have arranged with Mr. Sowerby some methods of observation by which I hope to obtain data for determination of these points.

If this be the case Limnocodium will hold a position intermediate between the Leptomedusæ and the Trachomedusæ; but as the greatest systematic importance must be attached to the structure and origin of the marginal vesicles, its affinity with the Leptomedusæ must be regarded as the closer of the two. GEO. J. ALLMAN

Physiology of the Freshwater Medusa

THE structure of this remarkable animal has already been investigated and described by Professors Allman and Lankester, with the result of showing that, although constituting a new genus, it is in all respects a true Medusa. After the publication of their papers I began to work out the physiology of the new form, and the following are the results which so far I have obtained.

The natural movements of the Medusa precisely resemble those of its marine congeners. More particularly, these movements resemble those of the marine species which do not swim continuously, but indulge in frequent pauses. In water at the temperature of that in the Victoria Lily-house (85° F.) the pauses are frequent, and the rate of the rhythm irregular—suddenly quickening and suddenly slowing even during the same bout, which has the effect of giving an almost intelligent appearance to the movements. This is especially the case with young specimens. In colder water (65° to 75°) the movements are more regular and sustained; so that, guided by the analogy furnished by my experiments on the marine forms, I infer that the temperature of the natural habitat of this Medusa cannot be so high as that of the water in the Victoria Lily-house. In water at that temperature the rate of the rhythm is enormously high, sometimes rising to three pulsations per second. But by progressively cooling the water, this rate may be progressively lowered, just as in the case of the marine species; and in water at 65° the maximum rate that I have observed is eighty pulsations per minute. As the temperature at which the greatest activity is displayed by the freshwater species is a temperature so high as to be fatal to all the marine species which I have observed, the effects of cooling are of course only parallel in the two cases when the effects of a series of higher temperatures in the one case are compared with those of a series of lower temperatures in the other. Similarly, while a temperature of 70° is fatal to all the species of marine Medusæ which I have examined, it is only a temperature of 100° that is fatal to the freshwater species. Lastly, while the marine species will endure any degree of cold without loss of life, such is not the case with the freshwater species. Marine Medusæ, after having been frozen solid, will, when gradually thawed out, again resume their swimming movements; but this freshwater Medusa is completely destroyed by freezing. Upon being thawed out, the animal is seen to have shrunk into a tiny ball, and it never again recovers either its life or its shape.

The animal seeks the sunlight. If one end of the tank is shaded, all the Medusæ congregate at the end which remains unshaded. Moreover, during the daytime they swim about at the surface of the water; but when the sun goes down they subside, and can no longer be seen. In all these habits they resemble many of the sea-water species. They are themselves non-luminous.

I have tried on about a dozen specimens the effect of excising the margin of the nectocalyx. In the case of all the specimens thus operated upon, the result was the same, and corresponded precisely with that which I have obtained in the case of marine species. That is to say, the operation produces immediate, total, and permanent paralysis of the nectocalyx, while the severed margin continues to pulsate for two or three days. The excitability of a nectocalyx thus mutilated persists for a day or two, and then gradually dies out—thus also resembling the case of the marine naked-eyed Medusæ. More particularly, this excitability resembles that of those marine species which sometimes respond to a single stimulation with two or three successive contractions.

A point of specially physiological interest may be here noticed. In its unmutilated state the freshwater Medusa exhibits the power of localising with its manubrium a seat of stimulation situated in the bell. That is to say, when a part of the bell is nipped with the forceps, or otherwise irritated, the free end of the manubrium is moved over and applied to the part irritated. So far, the movement of localisation is precisely similar to that which I have previously described as occurring in *Tiaropsis indicans* (*Phil. Trans.*, vol. clxvii.). But further than this, I find a curious difference. For while in *T. indicans*

these movements of localisation continue unimpaired after the margin of the bell has been removed, and will be ineffectually attempted even after the bell is almost entirely cut away from its connections with the manubrium; in the freshwater Medusa these movements of localisation cease after the extreme margin of the bell has been removed. For some reason or another the integrity of the margin here seems to be necessary for exciting the manubrium to perform its movements of localisation. It is clear that this reason must either be that the margin contains the nerve-centres which preside over these localising movements of the manubrium, or, much more probably, that it contains some peripheral nervous structures which are alone capable of transmitting to the manubrium a stimulus adequate to evoke the movements of localisation. In its unmutilated state this Medusa is at intervals perpetually applying the extremity of its manubrium to one part or another of the margin of the bell, the part of the margin touched always bending in to meet the approaching extremity of the manubrium. In some cases it can be seen that the object of this co-ordinated movement is to allow the extremity of the manubrium—*i.e.*, the mouth of the animal—to pick oft a small particle of food that has become entangled in the marginal tentacles. It is therefore not improbable that in *all* cases this is the object of such movements, although in most cases the particle which is caught by the tentacles is too small to be seen with the naked eye. As it is thus no doubt a matter of great importance in the economy of this Medusa that its marginal tentacles should be very sensitive to contact with minute particles, so that a very slight stimulus applied to them should start the co-ordinated movements of localisation, it is not surprising that the tentacular rim should present nerve-endings so far sensitive that only by their excitation can the reflex mechanism be thrown into action. But if such is the explanation in this case, it is curious that in *Tiaropsis indicans* every part of the bell should be equally capable of yielding a stimulus to a precisely similar reflex action.

In pursuance of this point I tried the experiment of cutting off *portions* of the margin, and stimulating the bell *above the portions of the margin which I had removed.* I found that in this case the manubrium did not remain passive as it did when the *whole* margin of the bell was removed; but that it made ineffectual efforts to find the offending body, and in doing so always touched some part of the margin which was still unmutilated. I can only explain this fact by supposing that the stimulus supplied to the mutilated part is spread over the bell, and falsely referred by the manubrium to some part of the sensitive—*i.e.*, unmutilated—margin.

But to complete this account of the localising movements it is necessary to state one additional fact which, for the sake of clearness, I have hitherto omitted. If any one of the four radial tubes is irritated, the manubrium will correctly localise the seat of irritation, whether or not the margin of the bell has been previously removed. This greater case, so to speak, of localising stimuli in the course of the radial tubes than anywhere else in the umbrella except the margin, corresponds with what I found to be the case in *T. indicans*, and probably has a direct reference to the distribution of the principal nerve-tracts.

On the whole, therefore, contrasting this case of localisation with the closely parallel case presented by *T. indicans*, I should say that the two chiefly differ in the freshwater Medusa, even when unmutilated, not being able to localise so promptly or so certainly; and in the localisation being only performed with reference to the margin and radial tubes, instead of with reference to the whole excitable surface of the animal.

All marine Medusæ are very intolerant of fresh water, and therefore, as the freshwater species must presumably have had marine ancestors,[1] it seemed an interesting question to determine how far this species would prove tolerant of sea water. For the sake of comparison I shall first briefly describe the effects of fresh water upon the marine species.[2] If a naked-eyed Medusa which is swimming actively in sea water is suddenly transferred to fresh water, it will instantaneously collapse, become motionless, and sink to the bottom of the containing vessel. There it will remain motionless until it dies; but if it be again transferred to sea water it will recover, provided that its exposure to the fresh water has not been of too long duration. I have never known a naked-eyed Medusa survive an exposure of fifteen minutes; but they may survive an exposure of ten, and generally survive an exposure of five. But although they thus continue to live for an indefinite time, their vigour is conspicuously and permanently impaired. While in the fresh water irritability persists for a short time after spontaneity has ceased, and the manubrium and tentacles are strongly retracted.

Turning now to the case of the freshwater species, when first it is dropped into sea water at 85° there is no change in its movements for about fifteen seconds, although the tentacles may be retracted. But then, or a few seconds later, there generally occurs a series of two or three tonic spasms separated from one another by an interval of a few seconds. During the next half minute the ordinary contractions become progressively weaker, until they fade away into mere twitching convulsions, which affect different parts of the bell irregularly. After about a minute from the time of the first immersion all movement ceases, the bell remaining passive in partial systole. There is now no vestige of irritability. If transferred to fresh water after five minutes exposure, there immediately supervenes a strong and persistent tonic spasm, resembling rigor mortis, and the animal remains motionless for about twenty minutes. Slight twitching contractions then begin to display themselves, which, however, do not affect the whole bell, but occur partially. The tonic spasm continues progressively to increase in severity, and gives the outline of the margin a very irregular form; the twitching contractions become weaker and less frequent, till at last they altogether die away. Irritability, however, still continues for a time—a nip with the forceps being followed by a bout of rhythmical contractions. Death occurs in several hours in strong and irregular systole.

If the exposure to sea water has only lasted two minutes, a similar series of phenomena are presented, except that the spontaneous twitching movements supervene in much less time than twenty minutes. But an exposure of even one minute may determine a fatal result a few hours after the Medusa has been restored to fresh water.

Contact with sea water causes an opalescence and essential disintegration of the tissues, which precisely resemble the effects of fresh water upon the marine Medusæ. When immersed in sea water this Medusa floats upon the surface, owing to its smaller specific gravity.

In diluted sea water (50 per cent.) the preliminary tonic spasms do not occur, but all the other phases are the same, though extended through a longer period. In sea water still more diluted (1 in 4 or 6) there is a gradual loss of spontaneity, till all movement ceases, shortly after which irritability also disappears; manubrium and tentacles expanded. After an hour's continued exposure intense rigor mortis slowly and progressively develops itself, so that at last the bell has shrivelled almost to nothing. An exposure of a few minutes to this strength places the animal past recovery when restored

[1] Looking to the enormous number of marine species of Medusæ, it is much more probable that the freshwater species were derived from them, than that they were derived from a freshwater ancestry.

[2] For full account, see *Phil. Trans.*, vol. clxvii., pp. 744-745.

to fresh water. In still weaker mixtures (1 in 8, or 1 in 10) spontaneity persists for a long time; but the animal gradually becomes less and less energetic, till at last it will only move in a bout of feeble pulsations when irritated. In still weaker solutions (1 in 12 or 1 in 15) spontaneity continues for hours, and in solutions of from 1 in 15 to 1 in 18 the Medusa will swim about for days.

It will be seen from this account that the freshwater Medusa is even more intolerant of sea water than are the marine species of fresh water. Moreover the freshwater Medusa is beyond all comparison more intolerant of sea water than are the marine species of brine. For I have previously found that the marine species will survive many hours' immersion in a saturated solution of salt. While in such a solution they are motionless, with manubrium and tentacles relaxed, so resembling the freshwater Medusa shortly after being immersed in a mixture of 1 part sea water to 5 of fresh; but there is the great difference that while this small amount of salt is very quickly fatal to the fresh-water species, the large addition of salt exerts no permanently deleterious influence on the marine species.

We have thus altogether a curious set of cross relations. It would appear that a much less profound physiological change would be required to transmute a sea-water jelly-fish into a jelly-fish adapted to inhabit brine, than would be required to enable it to inhabit fresh water. Yet the latter is the direction in which the modification has taken place, and taken place so completely that sea water is now more poisonous to the modified species than is fresh water to the unmodified. There can be no doubt that the modification was gradual—probably brought about by the ancestors of the freshwater Medusa penetrating higher and higher through the brackish waters of estuaries into the fresh water of rivers—and it would, I think, be hard to point to a more remarkable case of profound physiological modification in adaptation to changed conditions of life. If an animal so exceedingly intolerant of fresh water as is a marine jelly-fish may yet have all its tissues changed so as to adapt them to thrive in fresh water, and even die after an exposure of one minute to their ancestral element, assuredly we can see no reason why any animal in earth or sea or anywhere else may not in time become fitted to change its element.

GEORGE J. ROMANES

NOTES

THE Fiftieth Annual Meeting of the British Association will commence on Wednesday, August 25, 1880, at Swansea. The President Elect is Andrew Crombie Ramsay, LL.D., F.R.S., Director-General of the Geological Survey of the United Kingdom and of the Museum of Practical Geology. The Vice-presidents Elect are: The Right Hon. the Earl of Jersey, the Mayor of Swansea, the Hon. Sir W. R. Grove, D.C.L., F.R.S., H. Hussey Vivian, M.P., F.G.S., L. Ll. Dillwyn, M.P., F.L.S., J. Gwyn Jeffreys, LL.D., F.R.S.; and the General Secretaries: Capt. Douglas Galton, C.B., D.C.L., F.R.S., 12, Chester Street, Grosvenor Place, London, S.W., Philip Lutley Sclater, Ph.D., F.R.S., 11, Hanover Square, London, W.; Assistant-Secretary: J. E. H. Gordon, 22, Albemarle Street, London, W.; General Treasurer: Prof. A. W. Williamson, Ph.D., LL.D., F.R.S., University College, London, W.C.; Local Secretaries: W. Morgan, Ph.D., F.C.S., and James Strick, Swansea; and Local Treasurer: R. J. Letcher, Swansea. The Sections are the following:—A.—Mathematical and Physical Science.—President: Prof. W. Grylls Adams, F.R.S. Vice-Presidents: C. W. Merrifield, F.R.S.; C. W. Siemens, D.C.L., F.R.S. Secretaries: W. E. Ayrton; J. W. L. Glaisher, F.R.S.; Oliver J. Lodge, D.Sc.; Donald McAlister, B.Sc. (Recorder). B.—Chemical Science.—President: John Henry Gilbert, Ph.D., F.R.S. Vice-Presidents: I. Lowthian Bell, F.R.S.; William Crookes, F.R.S.; W. Chandler Roberts, F.R.S. Secretaries: Harold B. Dixon, F.C.S.; Dr. W. R. Eaton-Hodgkinson; P. Phillips-Bedson, D.Sc., F.C.S.; J. M. Thomson, F.C.S. (Recorder). C.—Geology.—President H. Clifton Sorby, LL.D., F.R.S. Vice-President: Prof. Archibald Geikie, LL.D., F.R.S., L. and E., Warington W. Smyth, F.R.S. Secretaries: W. Topley, F.G.S. (Recorder); W. Whitaker, F.G.S. D.—Biology.—President: A. C. L. G. Günther, M.D., F.R.S. Vice-Presidents: F. M. Balfour, F.R.S.; Prof. Newton, F.R.S.; F. W. Rudler, F.G.S. Secretaries: G. W. Bloxam, F.L.S. (Recorder); Prof. M'Nab, M.D. (Recorder); John Priestley; Howard Saunders, F.Z.S. E.—Geography.—President: Lieut.-General Sir John Henry Lefroy, C.B., K.C.M.G., F.R.S. Vice-Presidents:—Sir Henry Barkly, G.C.M.G., K.C.B., F.R.S.; Admiral Sir Erasmus Ommanney, C.B., F.R.S.; Lieut.-General Sir H. E. L. Thuillier, C.S.I., R.A., F.R.S. Secretaries: H. W. Bates, Assist.-Sec. R.G.S., F.L.S.; C. E. D. Black; E. C. Rye, Librarian R.G.S., F.Z.S. (Recorder). F.—Economic Science and Statistics.—President: George Woodyatt Hastings, M.P. Vice-Presidents: James Heywood, F.R.S.; William Newmarch, F.R.S.; Henry Richard, M.P. Secretaries: Noel A. Humphreys, F.S.S.; Constantine Molloy (Recorder). G.—Mechanical Science.—President: James Abernethy, C.E. Vice-Presidents: Prof. Osborne Reynolds, F.R.S.; Prof. James Stuart. Secretaries: A. T. Atchison (Recorder); H. Trueman Wood. The first general meeting will be held on Wednesday, August 25, at 8 p.m, precisely, when Prof. G. J. Allman, M.D., LL.D., F.R.S., L. & E., Pres. L.S., will resign the chair, and A. C. Ramsay, LL.D., F.R.S., V.P.G.S., Director-General of the Geological Survey of the United Kingdom, and of the Museum of Practical Geology, President-Elect, will assume the presidency and deliver an address. On Thursday evening, August 26, at 8 p.m., a *soirée*; on Friday evening, August 27, at 8.30 p.m., a discourse by Prof. W. Boyd Dawkins, F.R.S., on "*Primæval Man*"; on Monday evening, August 30, at 8.30 p.m., a discourse by Francis Galton, M.A., F.R.S., on "Mental Imagery"; on Tuesday evening, August 31, at 8 p.m., a *soirée*; on Wednesday, September 1, the concluding general meeting will be held at 2.30 p.m. On Saturday evening, August 28, Henry Seebohm, F.Z.S., will deliver a lecture to the operative classes on "The North-East Passage"; tickets can be purchased of the local secretaries. A room will be provided for the reception of apparatus and specimens illustrative of papers communicated to the sections. Excursions to places of interest in the neighbourhood of Swansea will be made on Thursday, September 2, and short excursions on the afternoon of Saturday, August 28.

WE regret to announce the death of M. J. M. Gaugain, the eminent French electrician, at the age of seventy years. We shall give some account of his life and work next week.

THE Committee for the erection of a statue to Gauss have just issued a note, from which we learn that on the 27th instant (11.30 A.M.) the statue—modelled, as we have previously announced, by Prof. Schafer of Berlin, and cast by Prof. Howaldt—is to be unveiled. The Committee will be happy to have the names of any English mathematicians or gentlemen who may be willing, or who intend, to take part in the festivities which are to accompany the ceremony of unveiling. Applications should be addressed at once to the Landsyndicus Otto, Gauss Monument Committee, Braunschweig (Brunswick).

A CORRESPONDENT, J. H. S., sends us the following notice of Dr. E. L. Moss, who has shared the fate of the *Atalanta*:—"It seems to have escaped the notice of the scientific world the loss it has sustained in the ill-fated *Atalanta*. Dr. Edward L.

Moss, one of the officers on board that vessel, besides being a surgeon of renown in the navy, was also, in the best sense of that phrase, a scientific man. His papers read before the British Association, and his remarks at sectional meetings over a large range of natural history subjects (I remember such particularly at the last Plymouth meeting) will be fresh in the minds of many. He was one who, always observing and storing up facts, at whatever part of the world he might be, could clearly and systematically arrange them, and also employ them if required with convincing force. Such opportunities for observation were many and various. His profession, and the high estimation in which he was held by the naval authorities making him a picked man for any special service. By no means his least accomplishment was the masterly way in which he wielded brush and pen. In the Arctic Expedition of 1875-76 he served on board H.M.S. *Alert*, and to the astonishment of every one brought back with him from that expedition a number of most beautiful finished water-colour paintings and sketches in black and white. These were all made on the spot in those far-off regions, and are, I believe, the only examples in colour, painted from nature, of those dreary, cold solitudes, and consequently were the first intimation to the majority of people of the gorgeous effects of colour to be seen there. I remember him telling me about the trouble it was to keep his pigments fluid and the devices he had to resort to to effect that result. Many of these paintings and drawings (in facsimile), with a vivid and most interesting descriptive narrative, were published in his book, 'Shores of the Polar Sea.'"

MR. W. A. FORBES, B.A., the Prosector to the Zoological Society, is leaving England by the mail steamer to-day for a short visit to the province of Pernambuco, Brazil. One of the chief objects of his visit will be to obtain specimens in spirit of the various Neotropical Mesomyodian *Passeres*, as well as of *Bucconidæ* and other birds. During his absence all communications relating to animals in the Gardens, &c., should be addressed to Mr. J. J. Lister, B.A., who has undertaken Mr. Forbes's prosectorial duties during the absence of the latter.

THE numerous friends of the late Prof. A. H. Garrod will be glad to hear that a "Garrod Memorial Fund" has been set on foot, with the object of reprinting, in a complete and separate form, all his published papers, both physiological and zoological. We hope to be able to announce further particulars shortly.

AMONGST the peculiar institutions of Paris are the street astronomers, who exhibit through their telescopes the moon, sun-spots, comets' tails, and other celestial objects, according to circumstances. Their charges vary from 1*d*. in the suburbs to 5*d*. on the Place de la Concorde or the Place Vendôme, where the instruments are not unworthy of a regular observatory. At the last monthly meeting of the scientific journalists M. Flammarion read an address sent to him by the corporation of these itinerant teachers of the marvels of the heavens. They state that from the beginning of the publication of the "Astronomie Populaire" the number of their customers has more than doubled.

THE establishment in Paris of a system of pneumatic clocks has not put a stop to the experiments for transmitting the observatory time by electricity not only to the several public clocks of Paris, but all over France, taking advantage of the telegraphic wires. A commission has been appointed by the Municipal Council of Paris to select between the several systems which have been proposed on competition.

AMONG the statues which have been exhibited in the *Salon* at the Palais de l'Industrie, Paris, two large monuments, to commemorate Denis Papin at Blois and Leverrier at Paris, have largely attracted public notice. The astronomer is represented erect, wearing his usual dress, and supporting in his left hand a celestial sphere; the right is pointing to the heavens.

THE U.S. Congress, we learn from the *Electrician*, has voted the sum of 15,000 dollars for a statue of the late Prof. Joseph Henry, to be placed in the grounds of the Smithsonian Institution.

THE *Colonies* draws attention to the establishment of a "School of Agriculture" at Canterbury, New Zealand, with the object of affording students the opportunity of acquiring a thorough knowledge of the science and practice of agriculture. The institution, which is under the direction of Mr. W. E. Ivey, M.R.A.C., F.C.S., is situated near Lincoln, about twelve miles from the city of Christchurch; and in addition to the school buildings—comprising lecture theatre, library, museum, chemical laboratory, &c.—has attached to it a farm of 500 acres of land of various qualities, from rich swamp pasture land to light and comparatively thin soil overlying shingle. A portion of the farm is devoted to experimental purposes to test the value of different methods of cultivation, the effect of manures on various crops, the qualities of indigenous and exotic grasses, and the suitability and comparative worth of new varieties of cereals, roots, fodder, and other plants. The students will be required to take part in the regular daily practical work of the farm, to acquire a practical knowledge of ploughing and every other kind of farm work, the use of implements and machinery, the management of stock, and the making of cheese and butter. They will also receive practical instruction in agricultural chemistry in the laboratory. Land surveying and levelling will be undertaken at suitable times for practice in the use of instruments, in measuring land, in harvest and other piece work, and for taking levels for drainage purposes. Lectures and instruction will be given to various subjects connected with agriculture, chemistry, botany, entomology, veterinary medicine, &c. Under the present rules candidates for admission as resident students are required to pass a preliminary examination; and must be between the ages of fifteen and nineteen.

FROM the reply of Earl Spencer last Thursday in the House of Lords to a question as to the teaching of agricultural science by the Science and Art Department, we are glad to find that at least the "utility" of science is beginning to be recognised in high places. "There was no more important matter," the Earl said, "than the application of science to the art of agriculture. Great attention had of late years been very properly called to the great aid which science gave to the various classes of manufacturers and producers; and that principle applied with quite as great force to agriculture as to any other art. That was especially the case at the present moment, when the country was inquiring narrowly into the whole of our agricultural system. If science could enable our agriculturists to produce more from the land than they had hitherto done it would add another to the many useful things it had been the means of accomplishing. It had been decided," the Earl went on to state, "by the department, in consequence of the pressure for accommodation for science classes and for instruction in various branches, not to have a special class for agricultural science this year, seeing that botany, geology, and chemistry, which were so intimately connected with agriculture, were taught separately. Since he had come into office, however, the department had decided that a class for agriculture should be held in August next."

THE Midland Union of Natural History Societies held its third annual meeting at Northampton on Thursday and Friday last, 17th and 18th inst., under the presidency of Sir Herewald Wake, Bart. The Union consists of twenty-four societies in the central counties, and numbers nearly 3,000 members. Its object is to encourage natural history studies, and to make local students residing far apart known to each other. So far its

success has been most marked. At Birmingham in 1878, at Leicester last year, and at Northampton this year, it has brought together naturalists from Nottingham, Burton, Leicester, Bedford, Peterborough, Hereford, Welshpool, Shrewsbury, Cheltenham, Stroud, Birmingham, and other places, and has afforded opportunities for intercourse between many who were previously strangers. The presidential address was brief, but interesting and suggestive. Lord Lilford took part in the proceedings, and read an admirable paper on ornithological topics. He exhibited nearly 200 specimens of birds taken chiefly in North Northamptonshire, the bulk of which he presented to the Northamptonshire Naturalists Society, of which he is president. The report of the council gave an outline of work done by the various societies in the Union during the past twelve months. In the evening an interesting scientific *conversazione* was provided in the Town Hall, and was largely attended. On Friday the members divided into two parties, one of which explored the geology of the district under the guidance of Mr. Hull; the other, led by Mr. Scriven, visited Castle Ashby, the seat of the Marquis of Northampton, and devoted the bulk of their time to botanising in Yardley Chase, &c. The meeting was in every way a success. The next year's meeting will be held at Cheltenham, and Dr. T. Wright, F.R.S., is the president elect.

M. DAUBRÉE, director of the French School of Mines, has published an essay on Descartes, in which he summarises the services rendered by that philosopher to science. He reminds his readers that Descartes advocated the theory of an igneous origin for the earth, and he enters into a lengthened discussion of the objections which may be raised against the theory of actual causes, as advocated by Lyell.

THE City and Guilds of London Institute for the Advancement of Technical Education has definitively accepted from Her Majesty's Commissioners for the Exhibition of 1851 a site for the Central Institution in Exhibition Road. The site is 300 feet long, and is between the temporary French and Belgian Courts. The advantages of this site are its proximity to the museums and libraries, and science and art schools of South Kensington. The central institution, when erected, will be used for the training of teachers, and will provide the highest technical instruction to students who have already obtained such a knowledge of the elements of science as is furnished by the School of Mines and other scientific institutions.

REPORTS continue to appear of the unusual quantity of drift ice met with in the North Atlantic by vessels sailing between this country and America. Do not these "numerous fields of ice" met with indicate an unusually early and extensive break-up of the Arctic ice-sheet, and extreme meteorological conditions in the Polar area?

MR. FRANK BUCKLAND has been awarded a gold medal and a decorated diploma of honour by the authorities of the Berlin International Fishery Exhibition.

PÈRE MARC DECHEVRENS, the Director of the Zikawei Observatory, near Shanghai, has lately published an important essay on the disastrous typhoon of July 31, 1879, accompanied by remarks on other typhoons in the autumn of the same year.

BY recent intelligence from New South Wales we learn that very rich silver lodes, with a large quantity of gold, had been discovered at the Nambuccra River, and that gold had also been found near Moama, on the Murray.

IN his just published Consular Report from Saigon, Mr. Tremlett furnishes some further notes respecting *hwang-nao*, to which we have referred on a previous occasion. It is said to be a bush, and to present something of the appearance of ivy; it is only found in mountains of lime-tone formation. It is said to cure the bite of the most venomous serpents, and has been successfully employed in curing cancer and principally leprosy, in the treatment of which it has never given other than satisfactory results. The native physicians, Mr. Tremlett remarks, distinguish thirty-six kinds of leprosy, the most common attacking the feet and hands; it is considered to be hereditary, and is usually contracted by children at the age of puberty. After some generations it has been noticed to confine itself to either the male or the female members of the family; the disease is considered contagious, which only would account for the large number of lepers in Tongking.

IN the last aëronautical ascent which was made at Rouen on Monday, June 13, by M. Jovis, M. Desmaret, one of the aëronauts, tried with success to take photographs of the land below. About fifteen different views were taken by him, and are wonderfully executed. The car had a hole in the centre, and the photographic apparatus was supplied with a patent obturator working in one-hundredth of a second. The photographs were of course taken by instantaneous process.

WE notice some interesting geological researches by M. Kontkevitch on the eastern slopes of the Oural Mountains. They will be an important addition to the well-known map of the western slope published some years ago by Prof. Möller.

WE have received the tenth volume of the *Memoirs* of the St. Petersburg Society of Naturalists, which contains, besides the minutes of meetings of the Society, a series of interesting papers:—A *résumé* of our knowledge on the Silurian in the Governments of St. Petersburg and Esthonia, by Prof. Friedrich Schmidt; on the ornithological fauna of the marshes of the district Uman (province Kieff), by G. Th. Göbel; a monograph on the sponges of the White Sea, by K. S. Merejkovsky; on the algæ of the Gulf of Finland, by Chr. Gobi; ornithological observations on the province of Ryazan, by P. Pavloff; on the birds of the tracts between the Amou and Kouvan-djarma Rivers, by M. Boutleroff; on the structure of the eye-like spots in certain fishes, by MM. Ousoff; and a flora of the Phanerogams of the Government of Tver, by A. A. Bakounin.

IN the *Sessional Proceedings* of June 4 of the National Association for the Promotion of Social Science will be found an extremely interesting discussion of the subject of educational pressure among girls, by various ladies connected with well-known girls' schools, and others.

THE additions to the Zoological Society's Gardens during the past week include two Rhesus Monkeys (*Macacus erythræus*) from India, presented respectively by Mr. W. Connell, and Mr. George L. Amlot; a Quica Opossum (*Didelphys quica*) from Demerara, presented by Capt. E. Ball; an Azara's Fox (*Canis azaræ*) from South America, presented by Mr. Edward Cooper; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, presented by Mrs. M. A. Brown; two Common Gulls (*Larus canus*), European, presented by Mr. J. Castell; a Dominican Gull (*Larus dominicanus, jv.*?) from New Zealand, presented by Capt. R. Bower; a —— Buzzard (*Buteo sp. inc.*) from Tasmania, presented by Capt. J. Seaborne; a Salt Water Terrapin (*Clemmys terrapin*) from North America, presented by Mr. A. D. Bartlett; a Common Ocelot (*Felis pardalis*) from Demerara, a Brown Capuchin (*Cebus fatuellus*) from Guiana, a Weeper Capuchin (*Cebus capucinus*) from Brazil, an Australian Crane (*Grus australasiana*) from Australia, deposited; two Virginian Deer (*Cariacus virginianus*) from North America, four Beautiful Finches (*Estrelda bella*) from Australia, purchased; a Leonine Monkey (*Macacus leoninus*) from Arracan, a Slow Loris (*Nycticebus tardigradus*) from Malacca, two Bay Bamboo Rats (*Rhizomys badius*) from India, two Sumatran

Wild Dogs (*Canis rutilans*) from Sumatra, a Javan Adjutant (*Leptoptilus javanicus*) from Java, received in exchange; a Wapiti Deer (*Cervus canadensis*), an Axis Deer (*Cervus axis*), born in the Gardens; three Siamese Pheasants (*Euplocamus prælatus*), two Horned Tragopans (*Ceriornis satyra*), two Peacock Pheasants (*Polyplectron chinquis*), four Mandarin Ducks (*Aix galericulata*), four Variegated Sheldrakes (*Tadorna variegata*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

Kepler's Nova of 1604.—The vicinity of this object is now favourably situate for observation in the evenings, and it is well worth while to keep a close watch upon one or two small stars near the position deduced for Kepler's object by Prof. Schönfeld from the observations of David Fabricius, which he considered preferable to those of Kepler and his pupils, given in his celebrated work, "De Stella nova in pede Serpentarii," more especially upon a star of the twelfth magnitude, or fainter, observed by Prof. Winnecke in 1875, which is close upon the place of a star of the tenth magnitude inserted on Chacornac's chart, but not afterwards found of this degree of brightness, and which is still more significant, almost exactly in the position of Kepler's object assigned by the observations of Fabricius. The most convenient reference-star in this neighbourhood is one meridionally observed by Argelander, No. 16872 of Oeltzen's Catalogue, a bright ninth magnitude, the position of which for the beginning of the present year is in R.A. 17h. 23m. 52·2s., N.P.D. 111° 23′ 22″; Schönfeld's place of Nova 1604 for the same epoch is in R.A. 17h. 23m. 26·9s., N.P.D. 111° 22′ 32″; Winnecke's star precedes Argelander's 33·2s., in 2″·7 less N.P.D. There is a somewhat brighter star preceding Argelander's 18·8s. with 1′·6 greater N.P.D., which, after several years' observation, has not exhibited any sensible fluctuation of magnitude. Attention should be chiefly directed to Winnecke's object, and it would be desirable to know its present magnitude, which some reader of this column may have the opportunity of putting upon record; we would, however, suggest its *frequent* observation.

There is no reason to suppose, notwithstanding the name of "temporary stars" which has been attached to them, that either Tycho Brahe's famous star of 1572, Kepler's of 1604, or the less conspicuous star discovered by Anthelm in 1670, have died out; on the contrary, in all three cases there are now small stars close upon the best positions which we can assign to the objects of those years, in which some fluctuations of brightness have been remarked after very careful observation.

Westphal's Comet (1852 IV).—In Mr. Chamber's useful manual of astronomy there is an oversight with respect to the orbit of the comet discovered by Westphal at Göttingen in June, 1852, the elliptic character of which was first made apparent by the computations of Mr. Marth towards the end of the same year. Elements derived from the earlier calculations are given in place of the definitive orbit deduced by Dr. Axel-Möller or the similar very completely-investigated orbit by the discoverer; hence the comet is credited with a period of revolution which is certainly ten years in excess of that belonging to the ellipse in which it was moving during its appearance in 1852. Dr. Axel-Möller's orbit is as follows:—

Perihelion passage, 1852, October 12·76278 G.M.T.

	°	′	″	
Longitude of perihelion	43	14	8	Mean equinox,
" ascending node ...	346	9	49	1852·0
Inclination	40	54	28	
Angle of excentricity	66	42	8·36	
Log. semi-axis major	1·1855845			

Motion—direct.

With these elements we find:—

Semi-axis major	15·3315
" minor	6·0637
Excentricity	0·9184625
Aphelion distance	29·4129
Perihelion distance	1·2501
Revolution	60·031 years

It is easy to see by what action the comet has been at some past time in all probability fixed in this orbit till similar perturbation recurs. In a true anomaly of 126° 30′ after perihelion or in ecliptical longitude 168° 52′, the comet is distant from the orbit of Jupiter only 0·36 of the earth's mean distance from the sun, and so close an approach of the two bodies would almost certainly result in the impression upon the comet of an orbit, materially differing from that in which it moved previously; this we know has occurred in several instances since the motions of comets have been rigorously investigated, a notable case being that of Brorsen's comet, which is now moving in an orbit into which it was thrown by its encounter with Jupiter in May, 1842.

GEOGRAPHICAL NOTES

In yesterday's *Times* is a letter from Mr. Thorndike Rice, giving details of the programme of the expedition to Central America, under the leadership of M. Charnay, for the exploration of the ancient monuments there, and to which we referred some time ago. Casts will be taken of all important bas-reliefs and inscriptions, part of which will be deposited in the Smithsonian Institution, and part sent to Paris. Details of the work of the expedition will be published from time to time in the *North American Review*.

Considerable attention is still attracted in Australia to the supposed existence in recent years of a survivor of Leichhardt's great exploring expedition, which disappeared in 1848. Numerous lengthy communications have been published by the Colonial press, which tend to confirm the belief that an aged European, not improbably Classen, as we have before mentioned, was living with the blacks near the Queensland border until some four years ago. A man has also come forward at Sydney and made a curious statement to the effect that he was a sailor on board a steamer which was sent by the South Australian Government in 1867 to take cargo to the Roper River, Gulf of Carpentaria, and that on landing some ten miles to the south of the mouth of that river he met natives who told him that three days journey up the river there was an old white man with a very long beard. The position mentioned would, it is thought, be very near the Elsey, where it has been before suggested that something might be found out about the fate of Leichhardt's party. It is to be regretted that the different persons who have contributed items of information did not come forward sooner with their contributions, however small, towards the solution of this mystery, as it might have been cleared up ere this.

The s.s. *Eira*, recently launched, left Peterhead on Saturday morning for the Arctic regions on a voyage of discovery. She has a crew of some twenty-five, and carries a photographer, the same who accompanied Capt. Nares, and a doctor. The steamer has been coaled and provisioned for two years, but her return is expected before that time.

The Ontario correspondent of the *Colonies and India* states that the construction of the long-talked-of railway across the island of Newfoundland has at length been decided upon; it will be 350 miles long, and will be of great benefit to the island.

In his report on the department of maps, charts, &c., at the British Museum, Mr. Major notes the undermentioned interesting additions during the past year:—A large English chart on parchment of the coasts of Brazil and Africa of the early date of 1647, bearing the legend, "made by Nicholas Comberford, dwelling neare to the West end of the Schoole House, at the XX signe of the Plat in Radcliffe, anno 1647." Also two illuminated and gilt MS. maps on parchment, the one of the coasts of Florida, New Spain, and Africa (1688), and the other of the West Indies (1698). These are by José da Costa Miranda. Another valuable acquisition is an important plan of Paris in seventy-two sheets, constructed by Varniquet, and finished in 1791, after thirty years' labour.

The new number of the Belgian Geographical Society's *Bulletin* opens with a paper on the geography of Lake Tanganyika, which was prepared by Lieut.-Col. Adan for the committee of the International African Association; it is illustrated by an interesting reproduction on one sheet of various maps, exhibiting the views of cartographers on the shape of the lake. The other papers are by Dr. Litton Forbes on the Island of Rotumah, and by M. A. J. Wauters on the African elephant.

SIR JOHN LUBBOCK ON THE HABITS OF ANTS

In a further contribution of his observations towards elucidating the economy and habits of these insects, laid before the last meeting of the Linnean Society (June 17), Sir John commenced

by relating his fresh experiments on their powers of communication. Among others a dead blue-bottle fly was pinned down, and after vain efforts at removal the selected ant hied home, and emerged with friends who slowly, and evidently incredulously, followed their guide. The latter starting off at a great pace distanced them, and they returned, again, however, to be informed, come out and at length be coaxed to the prey. In the several experiments with different species of ants and under varied circumstances, these seem to indicate the possession by ants of something approaching language. It is impossible to doubt that the friends were brought out by the first ant, and as she returned empty handed to the nest the others cannot have been induced to follow merely by observing her proceedings. Hence the conclusion that they possess the power of requesting their friends to come and help them. For other experiments testing the recognition of relations, although the old ants had absolutely never seen the young ones until the moment, some days after arriving at maturity, they were introduced into the nest, yet in all cases they were undoubtedly recognised as belonging to the community. It would seem, therefore, to be established that the recognition of ants is not personal and individual, and that their harmony is not due to the fact that each ant is acquainted with every other member of the community. It would further appear from the fact that they recognise their friends even when intoxicated, and that they know the young born in their own nest, even when they have been brought out of the chrysalis by strangers, indicating, therefore, that the recognition is not effected by means of any sign or password. With regard to workers' breeding, the additional evidence tends to confirm previously-advanced views, that when workers lay eggs males are always the issue of these. Without entering into details of instances it may broadly be affirmed that in the queenless nests males have been produced, and in not a single case has a worker laid eggs which have produced a female, either a queen or a worker. On the contrary, in nests possessing a queen, workers have been abundantly produced. The inference to these curious physiological facts leads to the presumption that, as in the case of bees, so also in ants, some special food is required to develop the female embryo into a queen. In Sir John's nests, while from accidents and other causes many ants are lost during the summer months, in winter, nevertheless, there are few deaths. As to the age attained, specimens of *Formica fusca* and *F. sanguinea*, still lively, are now four and others five years old at least. The behaviour to strange queens often results in their being ruthlessly killed; yet as communities are known to have existed for years, queens must occasionally have been adopted. With the view of trying how far dislike and passion might be assuaged by a formal temporary acquaintance a queen of *F. fusca* was introduced into a queenless nest, but protected by a wire cage, and after some days the latter removed, but the queen was at once attacked. Mr. McCook, nevertheless, relates an instance of a fertile queen of *Cremastogaster lineolata* having been adopted by a colony of the same species.

Such difference in conduct, Sir John suggests, may be due to his own ants having been living in a republic; for it is affirmed that bees long without a queen are strongly averse to adopt or accept another. Furthermore, if a few ants from a strange nest are put along with a queen they do not attack her, and if other ants are by degrees added the throne is ultimately secured. In pursuance of experiments to test the sense of direction, some ants were trained to go for their food over a wooden bridge made up of segments. Having got accustomed to the way, afterwards when an ant was in the act of crossing, a segment was suddenly reversed in direction, evidently to the ant's discomfiture; she then either turned round, or, after traversing the bridge, would return. When, however, similar pieces of wood were placed between nest and food, and the ant at the middle piece, those at the ends being transposed, the ant was not disconcerted. In other instances a circular paper disk was placed on a paper bridge, and when the ant was on the disk this was revolved, but the ant turned round with the paper. A hat-box with holes of entrance and exit pierced at opposite sides was planted across the line to the food; when the ant had entered and the box turned round, the ant likewise wheeled about, evidently retaining her sense of direction. Again, with the insect *en route*, when the disk or box with the ant within was merely shifted to the opposite side of the food without being turned round, the ant did not turn round, but continued in what ought to have been the direction to the food, and evidently was surprised at the result on arrival at the spot where the food had previously been. To ascertain whether ants make sounds audible to one another, the use of the telephone was resorted to, but the results were negative. These experiments may not be conclusive, for the plate of the telephone may be too stiff to be set in vibration by any sounds which the ants produced. As opposed to the opinion expressed by M. Dewitz, Sir J. Lubbock regards the ancestral ant as having been aculeate, and that the rudimentary condition of the sting in *Formica* is due to atrophy, perhaps attributable to disuse. A ground plan of the nest of *Lasius niger* is now given by Sir John, which exhibits an intricate, narrow, and winding entrance-passage; the main nest cavity is further supported by pillars, and here and there by islands; protected recesses obtain, evidently strategical retreats in times of danger. Studying the relations and treatment of the aphides, or plant-lice of the ants, Sir John clearly demonstrates that not only are the aphides kept and protected in the ants' nests, but the eggs of *Aphis* laid outside on the leaf-stalks of its food-plant in October, when exposed to risks of weather, are carefully brought by the ants into their nests, and afterwards tended by them during the long winter months until March, when the young ones are again brought out and placed on the young vegetable shoots. This proves prudential motives, for though our native ants may not lay up such great supplies of winter stores of food as do some of those found abroad, they thus nevertheless take the means to enable them to procure food during the following summer. The fact of European ants not generally laying up abundant stores may be due to the nature of their food. Insects and small animals form portions of their food, and these cannot always be kept fresh. They may also not have learnt the art of building vessels for their honey, probably because their young are not kept in cells like those of the honey bee, and their pupæ do not construct cocoons like those of the humble bee. Relatively to their size our English ants nevertheless store proportionally; for if the little brown garden ant be watched milking their aphides, a marked abdominal distension is observable. The paper concludes by the history and technical description of a new species of Australian honey ant. This corroborates Westmael's strange account of the Mexican species; certain individual ants being told off as receptacles for food, in short they become literally animated honey pots.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE committee of management of the Royal Agricultural College, Cirencester, have just established two scholarships of 25*l.* and 10*l.* respectively, to be open to all students of the college, and to be awarded three times every year in accordance with the results of the sessional examinations. The first award will take place after the Christmas examination of the present year. The vellum certificates and book prizes, and the gold medals, will be continued as heretofore.

THE first session of the representative Conseil Superieure de l'Instruction Publique of France was closed on June 17, by an address pronounced by M. Jules Ferry. The result of the deliberations has been to raise the standard of *Baccalaureat*, the first step in French classical honours; the time allotted to Greek and Latin in the course of studies has been curtailed at the expense of themes and versification, and allotted either to science or to living languages. The work of the next session will be to organise the scientific instruction. Sharp discussions are expected between the delegates who wish to organise a special course of instruction for sciences, and those who stick to the old scheme of making the preparation for the Government schools a supplement to classical instruction.

SOCIETIES AND ACADEMIES

London

Royal Society, May 27.—"On the Relation of the Urea to the Total Nitrogen of the Urine in Disease," by W. J. Russell, Ph.D., F.R.S., and Samuel West, M.B., Oxon.

In the valuable series of papers upon the excretion of urea, communicated by Prof. Parkes to the Royal Society, he showed that in health 90 per cent. of the nitrogen in the urine was eliminated in the form of urea. It seemed to us of considerable interest and importance to ascertain whether in disease this statement still held good, or whether, as indeed seemed probable, under altered conditions, nitrogen might not be excreted in some other form. With the view of determining this point, the following experiments were undertaken.

The cases upon which the observations were made fall into two groups—the first, a series taken at random from the hospital, the patients suffering from various diseases, and being under various conditions as regarded diet, muscular exertion, &c. In the second series, the patients were healthy, and placed under conditions as far as possible constant, the amount of diet being fixed, and the patients at absolute rest.

The first series, consisting of twenty-three observations, falls into several small groups. The relation of the urea-nitrogen to the total nitrogen was, in all cases, calculated out in percentage amounts (the total nitrogen being taken as 100), and the mean of each group of observations given.

The first group consists of six cases of pneumonia, and in these the urea-nitrogen represents 90 per cent. of the total nitrogen.

The second, of two cases of jaundice, with two determinations in each. The mean of the first giving 85·7 per cent.; of the second 90·2 per cent.

The third, of two cases of albuminuria, in which the mean is 86 per cent. In these observations the albumen was previously precipitated and removed. In a third case the determination was made without previously removing the albumen. In this latter, the percentage was 63·6.

The fourth group consists of a collection of cases of various kinds. One of pyæmia, one of typhoid fever, rheumatic fever, acute dysentery, pleurisy, hepatic abscess, and leucocythæmia, two of erysipelas, and two of diabetes, making eleven in all. The mean percentage of them all is 93·8.

The lowest percentage in this first series is found in the cases of albuminuria and of jaundice, a fact of interest as bearing upon the place of production of urea.

The second series consists of eighteen determinations made upon three cases, in which the diet was fixed and the patient in a condition of absolute rest.

These give a mean of 90·1 per cent. The mean of all the cases in the two series is 89·3, or, if the cases of albuminuria and jaundice be excluded, 91·3 per cent., and this agrees almost exactly with the results of Prof. Parkes' experiments, in which the mean arrived at is 91 per cent.

We may therefore assume that the urea-nitrogen may be taken as the measure of the total nitrogen, and that this may be approximately determined by adding 10 per cent. to the amount of urea-nitrogen.

This is, however, only true if the mean of a large number of observations be taken, for there is no fixed relation between, on the one hand, the amount of the urine and the amount of the solids in it, or on the other, between the amount of the various solids *inter se*.

The result, then, of our observations is to prove that the chemistry of the urine remains essentially the same in disease as in health, and that the generalisation of Prof. Parkes is true in either case. The urea may therefore be safely regarded as the measure of the total nitrogen, and as forming 90 per cent. of it.

"On the amount of Nitrogen excreted by Man at rest," by Samuel West, M.B. Oxon, and W. J. Russell, Ph.D., F.R.S.

The three patients, the subjects of this investigation, were all placed under the conditions of the most absolute rest, not being allowed to sit up in bed, or even indeed to feed themselves. Their diet was reduced till it was found that their health was suffering, and then increased until a condition was reached, which may be called one of "clinical equilibrium," when the health, so far as could be determined clinically, was perfect.

The patients were all suffering from the same affection, viz., aneurism, a disease which produces mechanical rather than constitutional symptoms, and in these cases, so long as the treatment was carried on, produced no symptoms at all, so that for all practical purposes the patients may be regarded as healthy men.

The condition of clinical equilibrium being reached, the amount of nitrogen in the food was determined by direct analysis.

In two of the cases the diet consisted of 10 ozs. of solids and 10 ozs. of liquids.

By calculation from Parkes' tables, this should yield 6·3 grms. of nitrogen. Analysis gave a somewhat higher number: in the first determination 7·07, and in the second 6·95.

In the third case the diet was 8 ozs. of solids and 8 ozs. of liquids, distributed in the same proportion. This by calculation from the preceding analysis should give about 5·6 grms. of nitrogen.

Comparing now the amount of nitrogen ingested in the food with the amount obtained from the urine, we find:—

	Nitrogen ingested.	Nitrogen in urine.
Case I.	7·0	8·6
,, II.	7·0	8·64
,, III.	5·6	6·4

In all the cases the amount in the urine is in slight excess of that in the food, so that we may fairly regard all the nitrogen here obtained as representing tissue waste, for there was no surplus in the food to increase the amount in the urine.

We obtain as the mean of these three cases $\frac{23·64}{3} = 7·87$, or approximately 8 grms., which we therefore are justified in regarding as the minimum amount of nitrogen a healthy adult man excretes per diem. This is equivalent to 17 grms., or 260 grains of urea.

It is interesting to compare with these observations the results obtained by the other methods of the investigation above referred to.

Ranke repeated upon man the experiments which Bischoff and

Voit had conducted upon the dog, and among them are two series of observations which illustrate the subject at present under consideration.

In the first no food at all was given, and the patients were kept at rest.

In one case 8 grms. of nitrogen were passed, in a second 10, and in a third 8·6. In a fourth case the amount was as low as 6. And in another series of observations upon himself, Ranke found the amount passed in two starvation days to be 8 and 8·6 grms.

Nicholson made three estimations in the case of starving prisoners, and found as the mean of three days 8·6 grms.

Many other observers have noticed the rapid fall in the amount of nitrogen excreted during starvation.

But the short duration of these experiments makes it probable that the minimum was not reached.

We have then 8 grms. as the mean of the only reliable determination at our command of the nitrogen excreted in the urine during starvation.

Prof. Playfair attacked the question from another side, by collecting from various sources the minimum diets upon which man could live, and to which he gave the name of subsistence diets, and by calculation the amount of nitrogen contained in them. This method gave him as a mean 9·2 grms., but his patients were none of them at absolute rest, but were performing during the day a certain amount of work. Edward Smith in the same way, by calculation from the diets of the spinners during the cotton famine, found a somewhat larger amount of nitrogen (12 grms.), which agrees with the amount of nitrogen contained in Playfair's second class of small diets, but in all these cases the effect of muscular exertion is not eliminated.

Unruh gives a series of three observations upon hospital patients kept at rest and placed upon a restricted diet.

In the first, a case of cancerous obstruction, the amount of nitrogen was 8 grms. (17·5 urea). But this case is not altogether satisfactory, from the amount of wasting accompanying this disease.

The other two were cases of syphilis placed upon fever diet, and kept at rest for the sake of the experiments; the first passed 8·6 grms. (18·6 urea), the second 7·5 grms. (16·2 urea).

The mean of these three cases is 8 grms. (17·5 urea).

The general results of the various series of observations may be roughly tabulated thus:—

I. Starvation. 8 grms.
II. Non-nitrogenous food. 8 grms.
III. Subsistence diet. 9 grms.
IV. Insufficient diet. 8 grms.
V. Clinical equilibrium. 8 grms.

A remarkable coincidence, considering the variety of the methods employed and the different conditions under which the determinations were made.

We may therefore conclude that the minimum amount of nitrogen excreted by a healthy adult man is on the average 8 grms. in the twenty-four hours, this being equivalent to 17·5 grms., or to 260 grains of urea.

Geological Society, June 9.—Robert Etheridge, F.R.S., president, in the chair.—John Burn Anstis du Sautoy and Rev. John Cowley Fowler, B.A., were elected Fellows; Prof. G. Dewalque, Liége, a Foreign Member, and Prof. Leo Lesquereux, Columbus, U.S., a Foreign Correspondent of the Society.—The following communications were read:—On the occurrence of marine shells of existing species at different heights above the present level of the sea, by J. Gwyn Jeffreys, F.R.S., Treas. G.S. This paper resulted from the author's examination of the mollusca procured during the expeditions of H.M.SS. *Lightning* and *Porcupine* in the North Atlantic. He stated that he found several species of shells living only at depths of not less than between 9,000 and 10,000 feet, which species occurred in a fossil state in Calabria and Sicily at heights of more than 2,000 feet, such depths and heights together exceeding the height of Mount Etna above the present level of the Mediterranean. He then gave an account of the post-tertiary deposits in Europe, Asia, and North America, to show their various heights, and especially of the raised beach on Moel Tryfaen in Caernarvonshire, which was from 1,170 to 1,350 feet high. Some of the shells in that deposit were boreal, and did not now live in the adjacent sea. The author stated that no shells of a peculiarly northern character had been noticed in the west or south of England. He then questioned the permanence and even the antiquity of the present oceanic basins, from a consideration not only of the fauna which now inhabits the greatest depths, but also of the extent of oscillation which had prevailed everywhere since the Tertiary period. A complete list of the Moel Tryfaen fossils was given, to the number of sixty, besides three distinct varieties, of which number eleven were Arctic or northern, and the rest lived in Caernarvon Bay. All of these fossils were more or less fragmentary.—On the pre-Devonian rocks of Bohemia, by J. E. Marr, B.A., F.G.S. The author commenced with a brief notice of the pre-Cambrian rocks, which are gneisses and schistose limestone with intrusive eclogite; over these lie unconformably green grits, ashes, breccias, hornstones (étage A of Barrande), which the author considers to represent the Harlech group of Wales. Étage B is unconformable with this, but conformable with C, which contains the "primordial" fauna. D contains the colonies. E to H are Silurian, and more calcareous than these underlying them. The base of the group is unconformable with those beneath. The lithological characters of the various beds were described. The following are the associated igneous rocks:—Granite, quartz feltzite, porphyrite, mica-trap, diabase, diorite, eclogite. Of these brief descriptions were given. The author gave a comparison of the various shales with English deposits. The pre-Cambrian series much resemble the Dimetian and Pebidian of Wales, the latter being étage A; étage B, the Harlech; étage C, the Menevian, probably a deep-water deposit, as is indicated by the abnormal size of the eyes of its Trilobites; the lowest bed of étage D probably represents part of the Lingula flags of Britain. D, α, 1, β, seems to represent the Tremadoc shale of Britain, and, like it, contains pisolitic iron-ore. Representatives also of the Arenig and Bala beds are found. A slight unconformity marks the base of the Silurian. Three graptolitic zones occur. The lowest, or *Diplograptus* zone, identical with the Birkhill shales, contains thirteen species of graptolites; the next, or *Priodon* zone (four species) resembles the Brathay flags; the upper, or *Colonies* zone (five species), resembling the Upper Coldwell beds of the Lake-district. Above these follow representatives of Wenlock, Ludlow, and probably of the Passage beds. The author, with the evidence of these, discussed the "colonies" theory of M. Barrande, pointing to the non-intermixture of species, notwithstanding the irregular repetition of the zones, the non-occurrence of these colony species in intermediate beds, and other reasons. The stratigraphy and palæontology of several of these colonies were discussed in detail, showing it to be more probable that their apparent intercalation with latter faunas is due to repetition by faulting.—On the pre-Cambrian rocks of the North-Western and Central Highlands of Scotland, by Henry Hicks, M.D., F.G.S. The author, after examination, considers the rocks of the following districts to be wholly or in part pre-Cambrian:—(1) *Glen Finnan, Loch Shiel to Caledonian Canal*; (2) *Fort William and Glen Nevis*; (3) *Ballachulish, Glen Coe, and Black Mount*; (4) *Tyndrum to Callander*. The author states that the Silurian (and Cambrian) rocks flank the pre-Cambrian in lines from north-east to south-west, and overlap Ben Ledi on the south side. Thus here, as elsewhere, subsequent denudation has removed enormous masses of the more recent rocks, only here and there leaving patches of these in folds along depressions in the old pre-Cambrian floor.

EDINBURGH

Royal Society, May 17.—Mr. D. Milne Home, vice-president, in the chair.—Mr. J. B. Haycraft, M.B., B.Sc., read a paper on a method for the quantitative estimation of urea in the blood. The method depended upon the fact that one can dialyse the fluid parts of blood into alcohol, into which the urea passes in a very pure form. The alcohol containing the urea is evaporated, the residue washed with petroleum ether, re-extracted, and estimated after the method of Huefner. This method yields urea from so small a quantity of blood as 10 cc., and shows that more is present than was formerly conjectured, there being on an average 35 parts per 100,000.—Mr. Patrick Geddes, in his paper on the phenomena of variegation and cell multiplication in a species of Enteromorpha, pointed out that the development of colourless cells in this alga was by a process of budding into the intercellular spaces between the coloured cells, so that both kinds of cell-multiplication, by fission and by budding, were exemplified in the same plant.—Prof. Tait gave a communication on the accurate measurement of high pressures. For pressures up to a few tons the behaviour of nitrogen had been thoroughly investigated (at least at one temperature). By comparison with a nitrogen compression gauge, a scale could be

constructed for a pressure gauge registering by the compression of the walls of a thinnish glass cylinder containing mercury; and this scale could be applied as long as the limits of elasticity, as defined by Hooke's law, were not exceeded. To determine when these limits were being approached, a similar glass cylinder with thicker walls was to be compared with the former one, which would be the first to deviate. This second gauge, with its higher limits of elasticity, could then be used for the higher pressures; and when its indications began to deviate from Hooke's law, a third and still stronger gauge could be substituted, its constants having been determined similarly by comparison with the second gauge. And thus a series of graduated gauges could be constructed to measure extremely high pressure; and at length when the pressure was such as to crush glass, a steel gauge constructed on somewhat similar principles could be substituted, being graduated first by comparison with the strongest glass gauge. Thus accurate measurements of high pressures could be obtained up to the point at which the compressing apparatus itself would begin to give way.—Mr. D. Milne Home, as convener of the Boulder Committee, presented the sixth report, and gave a notice of its chief features.—Prof. Turner exhibited a curious collection of natural masks and skulls from New Guinea and neighbouring islands.

Vienna

Imperial Academy of Sciences, April 15.—Observations on the deadening of torsion oscillations by internal friction, by Dr. Klemencic.—Studies on the decomposition of simple organic compounds by zinc powder; I. alcohols, by Prof. Ludwig.—On the action of some metals and metalloids on phosphorus oxychloride; and the existence of Leverrier's phosphoric oxide, by H. H. Renitzer and Goldschmidt.—On the saltness of water in the Norwegian North Sea, by Herr Tornöe.—New methods of finding mean geometric proportions, by Herr Zimels.—On the former and present position of geology and geogony, and the methods of research in these directions, by Dr. Boué.—Geological observations in Southern Calabria, by Dr. Burgenstein and Herr Nöe.—Radiant electrode-matter, by Dr. Puluj.

Paris

Academy of Sciences, June 14.—M. Edm. Becquerel in the chair.—The following papers were read:—On papaïne; contribution to the history of soluble ferments, by M. Wurtz. Alcohol precipitates from the juice of *papaya*, a principle of variable composition, but, when purified by dialysis, approximating to albuminoid matters. Papaïne purified with subacetate of lead has the composition and characters of such matters. The rapid liquefaction of fibrine by papaïne may occur in presence of prussic, boric, or even carbolic acid (conditions excluding microbes).—Geological history of the English Channel (second part), by M. Hébert.—Craniology of African negro races; non-dolichocephalic races, by M. de Quatrefages. The ninth volume of the "Crania Ethnica" finishes the account of negro races, and enters on the yellow or Mongolic races. M. Hamy finds in Africa that not only in individuals, but in entire populations occupying considerable spaces, and in some instances extending through about four-fifths of the Continent from east to west, there is an absence of dolichocephaly. One portion of these, marked also by small stature, are sub-brachycephalic generally, but sometimes reach brachycephaly; M. Hamy calls them Negrillos. He characterises various races that have hitherto been confounded.—New experiments on the resistance of Algerian sheep to spleen-disease, by M. Chauveau. The twelve European sheep tested all died after a single inoculation. Of forty-seven Algerian sheep, thirty-nine proved resistant after repeated inoculations.—M. Stas was elected Correspondent in Chemistry in room of the late M. Zinin.—On the value of gravity at Paris, by M. Peirce. He considers (from certain corrections) that the value hitherto given should be increased by one-ten-thousandth.—Determination of a function with only one variable, in a given interval, according to mean values of this function and of its successive derivatives in this interval, by M. Leauté.—On the resolution of the equation $x^n + y^n = z^n$, in whole numbers, by M. Lefébure.—Experimental researches on magnetic rotatory polarisation in gases, by M. Henri Becquerel. The memoir presented relates chiefly to various small corrections in his direct measurements, the most important being due to influence of magnetism on the glass closing the tubes. For the gases nitrogen, carbonic acid, protoxide of nitrogen, and olefiant gas (not for oxygen), he finds the magnetic rotations for rays of different wave lengths nearly in inverse ratio of the square of the wave-lengths as for non-magnetic solid bodies and liquids. The intimate connection of the rotation with the refractive index is shown. Oxygen, curiously, gives with red rays a rotation a very little above that with green (in the other gases the deflection is greater for green rays in the ratio of about 1·50). This may be connected with the very magnetic character of oxygen.—On the constancy of the proportion of carbonic acid in the air, by M. Schlœsing. He calculates that the sea holds in reserve a quantity of CO_2 disposable for exchange with the air ten times greater than the whole quantity in the atmosphere, and much greater, *a fortiori*, than the variations of this quantity; hence a strong regulative action on the amount of aërial CO_2.—On causes which tend to warp the girders of iron bridges and means of planning these girders so as to resist warping influences, by M. Périssé.—On the transcendants which play an important part in the theory of planetary perturbations, by M. Darboux.—M. Gaugain's death was announced.—On the figure of the planet Mars, by M. Hennessy.—On the equivalence of forms, by M. Jordan.—The tensions of saturated vapours have different modes of variation according as they are emitted above or below the point of fusion, by M. De Mondesir.—Action of bromide of methyl and of iodide of methyl on monomethylamine, by MM. Duvillier and Buisine.—On the transformation of terebenthene into cymene, by M. Bruère.—Preparation of indoline and its compounds, by M. Giraud.—On the existence of a lymphatic circulation in *Pleuronectes*, by M. Jourdain. The appearances in *Platessa vulgaris*, Cuv., and *Plat. flesus*, Cuv., are described. There are vessels which convey the lymph to peripheric parts, and others which bring it to a central reservoir. Also, the lymph seems to be aërated in vessels in the branchiæ. The lymph-reservoir has no intrinsic muscles (to effect the circulation), but the fibres acting on it seem to belong to the respiratory apparatus.—On the physiological action of *Thalictrum macrocarpum*, by MM. Bochefontaine and Doassans. *Thalictrine*, the active principle of this plant (found in a certain part of the Pyrenees), acts first on the central encephalo-medullary nervous system, then on the heart, arresting the functions; it affects nervous excito-motricity, and diminishes muscular contractility. It resembles aconitine, but is not so active.—On the micrographic analysis of water, by M. Certes. He treats water with a 1·5 per cent. solution of osmic acid (1 cc. of this to 30 to 40 cc. of water); the acid kills any organisms present without deforming them; they sink to the bottom and may be examined microscopically. Some colouring reagents mixed with dilute glycerine may also be used.—On the place of formation of adventive roots of monocotyledons, by M. Mangin.

THE SACRED BOOKS OF THE EAST

The Sacred Books of the East. Edited by F. Max Müller. Vols. iv., v., and vii. (Clarendon Press, 1880.)

THE great work upon which Prof. Max Müller is engaged goes on apace. Volume after volume issues from the University Press containing the principal portions of the sacred literature of the East translated by competent scholars. The materials for a science of religion are being rapidly accumulated. The grand conception of a science which shall trace the development and relations of the religions of the world and determine the laws that have presided over their birth, their growth, and their decay is no longer a dream of the distant future. Before many years are over the materials will be in our hands for realising that conception, if indeed it is ever to be realised at all.

The fourth and fifth volumes of the series introduce us to Zoroastrianism, the great Puritan religion of the Aryans, and thus the counterpart of Mohammedanism in the Semitic world. The fourth volume contains M. Darmesteter's translation of the Vendîdâd, a compilation of religious laws and mythological tales which forms the first part of the Avesta or Zoroastrian bible. The two other parts consist of the Vispêrad or litanies for the sacrifice, and the Yasna, which includes five hymns or Gâthâs written in a peculiar dialect and constituting the oldest portion of the Avesta. Besides these the Parsis also reverence the Khorda Avesta or Small Avesta, comprising short prayers, the Yashts or hymns of praise, and several other fragments.

These are all that is left of a much larger body of sacred literature which once existed among the disciples of Zoroaster. According to Parsi tradition, out of the twenty-one Nosks or books revealed to the Mazdean prophet one only, the Vendîdâd, remains complete, and though this tradition cannot be accepted in its literal form, there is abundant evidence that the Parsis have saved only scattered fragments out of the wreck of their sacred books caused by Greeks, by Christians, and by Mohammedans. In their present shape, moreover, these fragments do not go back beyond the age of the Sassanians, indeed they bear traces of even later modernisation; but the basis upon which they rest, the leading ideas they embody, and numerous passages that are imbedded in them are of much earlier date. If we may trust Dr. Oppert's translation of the Protomedic transcript of the inscription of Darius Hystaspis at Behistun, it was that Persian monarch who ordered the Avesta or "law" and the Zend or "Commentary" to be restored after the religious disturbances of the Magian usurpation. At any rate there can be little doubt that both existed before the foundation of the Persian Empire.

But like all other religions, Mazdeism developed and became changed in the process of time, and this development and gradual change may be read in the records of its sacred books. M. Darmesteter points out the untenability of the view which made it at the outset a revolt against the old Vedic religion of the Eastern Aryans; on the contrary, it grew naturally out of the elements, religious and mythological, which we see reflected in the Rig-Veda of India, and even after taking shape and consistency, after the days of Darius and the Sassanians, it still continued to grow. In the hands of its priests it became more and more rigorous and ceremonial; ancient texts were misinterpreted, and the misinterpretation carried out to its logical consequences.

In the fifth volume Dr. West introduces us to a later phase of Zoroastrian belief. He translates for us the Pahlavi texts, the Bundehesh, the Zâḍ-sparam, the Bahman Yasht, and the Shâyast lâ-shâyast, which are translations and explanations of the older Avesta. The Zend language had become obsolete, and the books written in it accordingly required to be translated and interpreted. The Pahlavi texts have, therefore, preserved portions of the ancient Zoroastrian scriptures which would otherwise have been lost. The Pahlavi is the language of mediæval Persia, the daughter of the Persian of Darius and his successors, and the niece of the Zend dialect of the Avesta. Our acquaintance with it practically begins with the inscriptions of Arṭakhshîr-i Pâpakân (A.D. 226–240) the founder of the Sassanian dynasty, and ends with Parsi writings, one of the latest of which is dated A.D. 881. The Pahlavi alphabet is an exceedingly difficult one; its letters have been corrupted to a prodigious extent, so that a large number of them are written exactly alike. The difficulties in the way of reading it may therefore be imagined. Pahlavi texts, however, are not always written in the Pahlavi alphabet; sometimes the Zend alphabet of the Avesta, sometimes the modern Persian alphabet, is used instead.

But the reading of these texts is further complicated by the introduction of Semitic words, which have, however, to be replaced in pronunciation by their Persian equivalents. Thus what is written *malkân malkâ*, "king of kings," would have to be pronounced *shâhân shâh*. The same phenomenon meets us in the cuneiform inscriptions, where an Accadian word often occurs in an Assyrian text, for which its Assyrian equivalent has to be substituted in reading, and so too in modern Japanese Chinese words are written but translated into Japanese by the reader. The usage of Pahlavi seems to be ancient, since the cuneiform alphabet of the Achæmenian inscriptions was obtained by Darius by translating a certain number of Assyrian ideographs into Persian and then setting apart the initial sound of the Persian word as the alphabetic value of the ideographic character. In addition to these Semitic logograms the Parsis also gave a conventional pronunciation to certain obsolete Persian words, the true pronunciation of which they had forgotten and were unable to recover owing to the obscurities of Pahlavi writing, and the employment of these two kinds of logograms is termed Huzvâresh.

The seventh volume contains a translation by Prof. Jolly of the Vishnu-sûtra, a semi-inspired Hindu law-book belonging to one of the schools who studied the Black Yajur Veda, and closely related to the famous Code of Manu. It has been revised by a Vishnuitic editor of comparatively recent date, but the substance of it goes back to an early time, before the introduction of *sati* or widow-burning, or even, it may be, the rise of Buddhism. It will be interesting to the lawyer as well as to the student of religion, who will be tempted to compare it with the book of Leviticus. Its minute and absurd

regulations as to ceremonial expiation and penance, its tyrannous assertion of Brahminical domination, and its unpractical and unspiritual character will illustrate the condition to which a religion may be brought by mere subtlety and barren meditation, divorced from active life and influenced by an interested priesthood.

A. H. SAYCE

EVOLUTION OF THE VEGETABLE KINGDOM

Versuch einer Entwicklungsgeschichte der Pflanzenwelt, insbesondere der Florengebiete seit der Tertiärperiode. Von Dr. Adolf. Engler. I. Theil. Die Extratropischen Gebiete der Nördlichen Hemisphäre. Mit einer chromolithographischen Karte. 8vo. pp. 202. (Leipzig: Verlag von Wilhelm Engelmann, 1879.) Essay of a History of the Evolution of the Vegetable Kingdom, especially of the Floral Areas since the Tertiary Period. Part I.—The Extratropical Regions of the Northern Hemisphere.

PHYTOGEOGRAPHY still presents many difficult problems, the final solution of some of which is extremely unlikely, though patient research will doubtless bring us much nearer the truth than we have yet reached. The latest comprehensive work on the subject (Grisebach's "Vegetation der Erde") is a very good exposition of the existing distribution of plants, but it is nothing more. Since the promulgation of the theory of descent, however, the study of the dispersion of plants has entered upon a fresh phase, and it has received the attention of some of the ablest minds engaged in botanical pursuits; and with the ever-increasing geological evidence of the composition of the floras of former periods there is a good prospect of a real advance in this branch of science. Unfortunately there is a tendency to travel far beyond a point warranted by the evidence. This remark specially applies to the determination of many of the fossils of the earliest Tertiary times. Whether fresh discoveries will prove the correctness or the incorrectness of Unger's "New Holland in Europe," we do not venture to predict, though we think the latter; but we agree with Saporta that most of the assumed determinations are better designated by such terms as affiliation and collocation (*assimilation et rapprochement*). Dr. Engler is not an unknown worker in phytogeography, for in his various monographs, especially in that of the genus *Saxifraga*, he has set forth the views which he, in some respects, more fully elaborates in the work before us. The essay itself is preceded by thirty-six formulated leading ideas (*leitende Ideen*), which may, for our purpose, be reduced to one, namely, the relation of evolution and geological changes to distribution. Dr. Engler endeavours to trace the descent and migration of the vegetation of the regions under consideration since the Tertiary period by the aid of geological and recent evidence, but for various reasons he does not go back beyond the Miocene period. In his conception of the Miocene period he is in accord with Prof. Heer, who, he thinks, has easily refuted the arguments adduced by Mr. Starkie Gardner in support of his opinion that much of what Prof. Heer regards as Miocene is referable to the Eocene period. The author divides his subject into five sections and eighteen chapters. In the first section he treats of the development of the flora of North America from the Miocene period to the Glacial epoch; the second is devoted to the development of the flora of Eastern and Central Asia since Tertiary times; the third to the main features of the development of the Mediterranean flora since the Tertiary period; the fourth to the development of the high mountain flora before, during, and after the Glacial epoch; and the fifth to the consideration of the development of the floras of other countries influenced by the Glacial period. The map is constructed to show, as nearly as possible, the configuration of land and water in Tertiary times, the direction of the spreading and change of the vegetation during and after the gradual drying-up of the Tertiary seas, and the most important migratory routes of the Glacial plants. Disregarding the evolutionary element, which must necessarily be to a large extent purely speculative, Dr. Engler's essay is exceedingly interesting and instructive. The mere collocation of the facts bearing upon the subject renders it so, independently of the author's deductions therefrom. So far as the migratory part is concerned, it may be designated as an amplification, with some modifications, of the theory recently discussed by Dr. Asa Gray, Sir Joseph Hooker, Mr. Thiselton Dyer, and others. Dr. Engler does not find the contrast so great in the development of the Asiatic element in the vegetation of Eastern and Western North America, and there is no doubt of the existence of many more Asiatic types in Western North America than was formerly suspected. Diligent as the author has been in collecting evidence, he has overlooked some that he would have found useful. Thus at page 29 he seeks to explain the "extraordinarily interrupted distribution" of *Monotropa uniflora* and *Phryma leptostachya*, both of which he assumes to be limited to the Himalayas, North-eastern Asia, and Eastern North America. Now *Monotropa uniflora* is common in North America west of the Rocky Mountains, as evidenced by specimens and collectors' notes in the Kew Herbarium; and it likewise occurs in Mexico, New Granada, Sachalin, and the Corea. The distribution of *Phryma*, too, is by no means so restricted as Dr. Engler supposes. But these are minor details which do not affect the main issues.

Although evolution is the pervading feature of the work, the author nowhere attempts to point out the original types from which other species have descended, as he does in his monograph of the genus *Saxifraga*. Bunge, who devoted much time to the study of large genera, constructed a genealogical tree to illustrate the possible descent of the species of *Acantholimon*, but he admits that the result was eminently unsatisfactory. If so difficult to trace the descent of a genus having the distribution of *Acantholimon*, we may excuse Dr. Engler for being less successful on the evolution theme than he is on migration.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The Freshwater Medusa

I OBSERVE in Prof. Allman's article of last week (p. 178) on this organism, that he states that the article in question includes

"additional facts not contained in the paper" read by him to the Linnean Society.

Although Prof. Allman does not directly allude to my article of the week before (p. 147), I may assume that the statements which he makes in opposition to my conclusion that Limnocodium (Craspedacustes) belongs to the group of the Trachomedusæ were elicited by the publication of my results.

I intend in the July number of the *Quarterly Journal of Microscopical Science* to show in an illustrated memoir that, contrary to the conclusion of Prof. Allman, the tentacles of Limnocodium do resemble those of the Trachyline Medusæ in their insertion and in the possession of true (though rudimentary) peronia, as I stated in my original note and in my paper read to the Royal Society on June 17. I shall also show that my statement that the so-called lithocysts or marginal bodies have essentially the same structure as those of Trachyline Medusæ (being modified tentacles with an endodermal axis) is warranted by the developmental history of the bodies in question. Consequently I adhere to my original determination of the affinities of the new Medusa as one of the order Trachomedusæ, and cannot agree with Prof. Allman that its affinity with the Leptomedusæ must be regarded as the closer of the two.

Prof. Allman states that he has arranged certain methods of observation with Mr. Sowerby, by which he hopes to determine the developmental history of Limnocodium. It will be of the greatest interest to have this matter fully investigated, and to know what are the methods which Prof. Allman has devised to this end. Mr. Sowerby informs me that at present he has undertaken no experiments of the kind excepting the isolation of specimens in two glass jars in the lily-house, which he carried out at my special request on June 15.

In the meantime I may say that I have fully satisfied myself that Limnocodium develops directly from the egg. When specimens are kept living in a glass jar under constant observation it is found that exceedingly small specimens of the Medusa make their appearance amongst the larger specimens. Mr. Sowerby had already determined this fact a fortnight ago, when I first was introduced by him to the Medusa. I have now, through his kindness, been able to examine several young phases of Limnocodium, the discovery of which is entirely due to him.

The youngest specimen which I have seen at present measured only the one-thirtieth of an inch in diameter, and I have had others under observation very little larger. The smallest was of a sub-spherical form without any aperture to the ectodermal investment. Four minute tentacles were sprouting near one pole of the spherical body, and between these rudiments of four others were seen. Within—the subumbrellar musculature was already developed and contracting at intervals. The four radial canals were also present, and, what is more remarkable, the sub-umbrellar cavity was already well marked, and within it the manubrium with the oral aperture. Yet the margin of the umbrella was still closed by a continuous ectodermal coat which, when perforated, would, I conceive, become the velum.

These minute embryos correspond very closely in appearance with the embryos of the well-known typical Trachomedusan Geryonia, as figured by Metschnikow in the *Zeitsch. für wiss. Zoologie*, vol. xxiv., Plate II., Figs. 12 and 15.

They leave no possibility of supposing that Limnocodium has, like most Leptomedusæ, a hydroid trophosome. In respect of its development as in other respects, Limnocodium is not more closely allied to the Leptomedusæ than to the Trachomedusæ, but is one of the Trachomedusæ.

A remarkable fact which I am not able to explain is the excessive rarity of females amongst the specimens of Limnocodium taken from the tank in Regent's Park. All the specimens which I have examined have been males. Females clearly enough must be present, or have been present amongst the shoals of males—whence the embryos discovered by Mr. Sowerby.

It is a known fact among Trachyline Medusæ that in some species males are excessively abundant, and even in some species females have never been detected. Thus again Limnocodium agrees with the Trachyline Medusæ.

One word more with regard to the name of the new Medusa. Whilst I waive the right of priority for the generic term Craspedacustes, and adopt Prof. Allman's term Limnocodium, I feel it to be only right to maintain the association of Mr. Sowerby's name with this discovery, which I had originally proposed, and I shall accordingly henceforth speak of the Medusa as *Limnocodium Sowerbii*, Allman and Lankester.

E. Ray Lankester

Aqueous Vapour in Relation to Perpetual Snow

Some twelve years ago I gave (*Phil. Mag.*, March, 1867, "Climate and Time," p. 548) what appears to be the true explanation of that apparently paradoxical fact observed by Mr. Glaisher, that the difference of reading between a thermometer exposed to direct sunshine and one shaded *diminishes*, instead of increases, as we ascend in the atmosphere. This led me to an important conclusion in regard to the influence of aqueous vapour on the melting-point of snow; but recent objections to some of my views convince me that I have not given to that conclusion the prominence it deserves. I shall now state in a few words the conclusion to which I refer.

The reason why snow at great elevations does not melt but remains permanent, is owing to the fact that the heat received from the sun is thrown off into stellar space so rapidly by radiation and reflection that the sun fails to raise the temperature of the snow to the melting-point; the snow evaporates, but it does not melt. The summits of the Himalayas, for example, must receive more than ten times the amount of heat necessary to melt all the snow that falls on them, notwithstanding which the snow is not melted. And in spite of the strength of the sun and the dryness of the air at those altitudes, evaporation is insufficient to remove the snow. At low elevations, where the snowfall is probably greater and the amount of heat even less than at the summits, the snow melts and disappears. This, I believe, we must attribute to the influence of aqueous vapour. At high elevations the air is dry and allows the heat radiated from the snow to pass into space, but at low elevations a very considerable amount of the heat radiated from the snow is absorbed in passing through the atmosphere. A considerable portion of the heat thus absorbed by the vapour is radiated back on the snow, but the heat thus radiated, being of the same quality as that which the snow itself radiates, is on this account absorbed by the snow. Little or none of it is reflected like that received from the sun. The consequence is that the heat thus absorbed accumulates in the snow till melting takes place. Were the amount of aqueous vapour possessed by the atmosphere sufficiently diminished, perpetual snow would cover our globe down to the sea-shore. It is true that the air is warmer at the lower level than at the higher level, and by contact with the snow must tend to melt it more at the former than at the latter position. But we must remember that the air is warmer mainly in consequence of the influence of aqueous vapour, and that were the quantity of vapour reduced to the amount in question the difference of temperature at the two positions would not be great.

But it may be urged, as a further objection to the foregoing conclusion, that as a matter of fact on great mountain chains the snow-line reaches to a lower level on the side where the air is moist than on the opposite side where it is dry and arid. As, for example, on the southern side of the Himalayas and on the eastern side of the Andes, where the snow-line descends some 2,000 or 3,000 feet below that of the opposite or dry side. But this is owing to the fact that it is on the moist side that by far the greatest amount of snow is precipitated. The moist winds of the south-west monsoon deposit their snow almost wholly on the southern side of the Himalayas, and the south-east trades the snow on the east side of the Andes. Were the conditions in every respect the same on both sides of these mountain ranges, with the exception only that the air on one side was perfectly dry, allowing radiation from the snow to pass without interruption into stellar space, while on the other side the air was moist and full of aqueous vapour absorbing the heat radiated from the snow, the snow-line would in this case undoubtedly descend to a lower level on the dry than on the moist side. No doubt more snow would be evaporated off the dry than off the moist side, but melting would certainly take place at a greater elevation on the moist than on the dry side, and this is what would mainly determine the position of the snow-line.

In like manner the dryness of the air will in a great measure account for the present accumulation of snow and ice on Greenland and on the Antarctic continent. I have shown on former occasions that those regions are completely covered with perpetual snow and ice, not because the quantity of snow falling on them is great, but because the quantity melted is small. And the reason why the snow does not melt is not because the amount of heat received during the year is not equivalent to the work of melting the ice, but, mainly because of the dryness of the air, the snow is prevented from rising to the melting-point.

There is little doubt but that the cold of the glacial epoch would produce an analogous effect on temperate regions to that

experienced at present on Arctic and Antarctic regions. The cold, although it might to some extent diminish the snowfall, would dry the air and prevent the temperature of the snow rising to the melting-point. It would not prevent evaporation taking place over the ocean by the sun's heat, but the reverse, but it would prevent the melting of the snow on the land during the greater part of the year.

In places like Fuego and S. Georgia, where the snow-fall is considerable, perennial snow and ice are produced by diametrically opposite means, as I have elsewhere shown, viz., by the sun's heat being cut off by clouds and dense fogs. In the first place the upper surface of the clouds act as reflectors, throwing back the sun's rays into stellar space; and in the second place, of the heat which the clouds and fogs absorb, more than one-half is not radiated downwards on the snow, but upwards into space. And the comparatively small portion of heat which manages to reach the ground and be available in melting the snow is insufficient to clear off the winter's accumulation.

JAMES CROLL

Artificial Diamonds

ON reading Mr. Hannay's communication to the Royal Society on the production artificially of crystallised carbon or diamond (*Proc.* Roy. Soc., vol. xxx., No. 204, May, 1880), in the course of which Mr. Hannay states that he has made eighty experiments, only three of which have been successful. In almost every case his iron or steel vessels, enormously thick in proportion to their small bore, have burst at a red heat or above it, by the pressure of the included hydrocarbon vapour.

Will Mr. Hannay permit me to suggest to him that if, instead of an enormously thick and difficult to weld up tube, he will inclose his materials in a comparatively thin one and then inclose that in another like tube shrunk on or contracted over the former, and so on to a third, or, if necessary, fourth tube, each possessing an initial tension upon those within it, he may thus obtain compound tubes either of wrought iron or steel easily welded staunch, and capable of withstanding any assignable amount of internal elastic pressure. This is the principle upon which, since 1855, all rifled artillery is constructed.

The Grove, Clapham Road, June 22 R. MALLET

A Fourth State of Matter

IN Mr. Crookes' communication on this subject (NATURE, vol. xxii. p. 153) occurs the sentence, "An isolated molecule is an inconceivable entity." This proposition would appear to me to be questionable. For if we cannot conceive an isolated molecule, how are we to conceive of two (or more) molecules, *i.e.*, conceive of matter at all? For the conception of two molecules involves the isolation of each in the mind, otherwise surely the two would be mentally blended into one. It is further said of a molecule, "Solid it cannot be." May not the external qualities ordinarily attributed to a "solid" be said to be those of a body possessing a certain amount of rigidity (*i.e.*, whose parts resist displacement) combined with a certain elasticity? Would not these be substantially the properties of a single vortex molecule, according to those who have investigated this subject? For it appears that such a molecule would be (perfectly) elastic, and inseparable into parts. At the same time it would seem that there would be nothing to prevent it from being harder or more rigid than any large scale solid (built up of such molecules?) with which we are acquainted.

"A fourth state of matter," as it appears to me, is a distinction which has something arbitrary about it. If (for instance) the æther be a gas, the mean length of path of whose minute molecules is not less than planetary distances—a proposition which it might not be easy to disprove directly—then this would be a mean path indefinitely greater than that of the molecules of the most rarefied gas. Would it, however, be legitimate to regard the æther (under this condition) as matter in "a fourth state"? This would seem, in my judgment at least, only to complicate the subject unnecessarily. For after all we are concerned in such cases with the mere quantitative difference of length of path. S. TOLVER PRESTON

London, June 28

Auroral Observations

IN order to get nearer, if possible, to the unravelling of the mysteries of the aurora borealis, I have in the course of the last two years endeavoured to procure a great number of observations of this phenomenon in Norway, Sweden, and Denmark. I have succeeded in engaging throughout the above-named countries several hundreds of observers, who, led only by scientific interest, have lent me their assistance, and from whom I have already received a considerable amount of information. These observations are to be continued, as there is reason to suppose that the aurora borealis in the near future will appear much more frequently than has been the case during the last years. Finland and Iceland will also now be drawn within the circle, and *it would be most desirable that similar observations were made also in Great Britain*, which country—especially in the maximum years of the appearance of the aurora borealis—certainly would yield characteristic contributions in this respect. I therefore take the liberty to invite friends of science to make such observations in accordance with the system which I have introduced in Scandinavia; a schedule for recording observations, along with the necessary instructions, will be sent to any one who, before the end of August, informs me of his name and address.

SOPHUS TROMHOLT

Bergen, Norway, June Professor of Mathematics

Other papers in Great Britain are requested kindly to give the above appeal a place in their columns.

The Hydrographic Department

AS you have been misinformed on several points respecting my connection with the Hydrographic Department, I request, both on public grounds and in ordinary fairness to myself, that you will insert the following corrections of statements in your article on this subject in NATURE, vol. xxii. p. 86.

My work on the Norwegian coast has not been "dignified into a hydrographical survey." That work, combined with my knowledge of the Norwegian language, charts, and pilotage, satisfied the hydrographer that I was competent to compile a "Norway Pilot." It is incorrect to represent that I have ever laid claim to anything more than that.

I have not made a "rude" or "ungenerous" attack on the Hydrographic Department. I have temperately stated facts which cannot be disproved, in the interests of hydrography, and to show the necessity for giving increased strength and efficiency to the department. It is no answer to these facts to disparage my own efforts in the cause, or to call me a small and obscure clique actuated by personal motives. The clique to which I belong is small indeed, for it consists only of myself. It may also be obscure, but it is untrue that I am influenced, in anything I may do, by other than public motives and a desire to further the interests of commerce and of hydrography.

The gravest error into which your informant has led you is the statement that the Hydrographic Department had confided to me, "mistakenly" or otherwise, the "*revision* of the sailing directions" for part of Norway. I *compiled* those sailing directions, as expressly stated in the official printed "Advertisement," signed by the hydrographer himself, and the department has done exactly the opposite of what your informant states; it has refused to allow me to *revise* my own work, and has consequently published an erroneous light list, which will be followed by an incomplete "Pilot." Against this procedure it is my obvious duty to protest. I am also bound to warn all those whom it may concern of the errors to which the department has deliberately given dangerous publicity.

The paper read before the Society of Arts brought the dangers along the trade route between England and Siberia to public notice in some detail, and contained other facts relating to neglected surveys and to charts compiled from antique and inadequate data, which it was right that merchants and seamen should be aware of. If my statements are accurate—and I challenge your informant to disprove any one of them—then the Society of Arts did useful service in accepting my paper. No good end can be gained by calling me names and accusing me of personal motives. Let my statements be disproved if your informant is able to disprove them. If he cannot do so, then those statements are incontrovertible witnesses to the fact that the Hydrographic Department is unequal to the demands upon it. Unsupported assertions that the department stands "well, and deservedly so, in the estimation of scientific circles," are of no weight when opposed to facts, which your informant cannot disprove, and apparently dares not face. GEORGE T. TEMPLE

The Nash, near Worcester, June 2

[WE have given publicity to Lieut. Temple's reply to the

notice on the Hydrographic Department which appeared in NATURE, vol. xxii. p. 86, on the grounds advanced by him in the first paragraph of his letter.

Our readers will scarcely receive Lieut. Temple's statement that that department has deliberately given dangerous publicity to errors. This would be contrary to the traditions, and certainly to the interests, of any public office connected with the practical and working world. But however this may be, is not the Hydrographic Department pursuing a prudent course in causing a revision to be made of Lieut. Temple's compilation by another authority? In the interests of navigation we think it is; for on a great stretch of coast like Norway, which, from its sinuous and broken character, can be reckoned by thousands of miles of sea-board, it is clearly unadvisable that dependence should be entirely placed on the efforts of one individual.

We are the more confirmed in this belief from a significant letter which lately appeared in the *Shipping and Mercantile Gazette* and in the *Daily News* from the Royal Norwegian Geographical Survey Office, dated Christiania, the 16th inst., written, as the writer alleges, "in order to correct the erroneous statements contained in Mr. Temple's paper (read at the Society of Arts) respecting the charts and descriptions of the Norwegian coast now existing."—ED.]

Curious Electric Phenomenon

AT about 4.30 p.m. this day a severe thunderstorm with a deluge of rain came up from the north-west and lasted about an hour. At 5.30 my wife was standing at the window watching the receding storm, which still raged in the south, just over Leicester, when she observed, immediately after a double flash of lightning, what seemed like a falling star, or a fireball from a rocket, drop out of the black cloud about 25° above the horizon, and descend perpendicularly till lost behind a belt of trees. The same phenomenon was repeated at least a dozen times in about fifteen minutes, the lightning flashes following each other very rapidly and the thunder consisting of short and sharp reports. After nearly every flash a fireball descended. These balls appeared to be about one-fifth or one-sixth the diameter of the full moon, blunt and rounded at the bottom, drawn out into a tail above, and leaving a train of light behind them. Their colour was mostly whitish, but one was distinctly pink, and the course of one was sharply zig-zagged. They fell at a rate certainly not greater than that of an ordinary shooting star. I have never witnessed a phenomenon of this kind myself, but my wife is a good observer, and I can vouch for the trustworthiness of her report.

Meteor

ON Friday, June 11, at 8.5 p.m., while the sun was still shining, I saw due east as near as I could judge, and about 30° above the horizon, a bright white meteor pass across about 10° or 12° from right to left with a slight downward course. Two or three hours later I saw a small one take a parallel course, but the other side the zenith.

Minerva Ornaments

DURING a recent visit to England I spent a considerable time in the Museum at South Kensington, and Dr. Schliemann's collection of antiquities was one of the objects in that museum which I was most desirous to see.

I should like to call attention to one point in regard to this collection of relics. Among others I saw a number of flat rounded pebbles, which, by chipping at the middle on both edges, have been brought into something like the shape of an hour-glass. These are marked "Minerva Ornaments." There are several other relics, the titles on which seemed to me to be, speaking within bounds, somewhat imaginative; such, for example, as the small pieces of gold plate on the κρήδεμνον, or headdress, where Dr. Schliemann sees the owl's head and two large eyes, "which cannot be mistaken"; but to name these flat pebbles "Minerva Ornaments" seems to trespass not a little beyond the due limits of the imagination when applied to science.

Stones of precisely the same shape and size, and cut in the same way, are common in this country, where Minerva was "an unknown goddess" before the arrival of the Christians. They are picked up on the banks of the rivers, and when placed in collections are ticketed "net-sinkers." I cannot doubt that Dr. Schliemann's "Minerva Ornaments" are only Trojan net-sinkers formed as those of the aboriginal inhabitants of this country, because the savage mind seems to have run in the same channel all over the world.

A Snake in Kensington Gardens

I WAS considerably surprised this evening at finding the lifeless body of a snake about one hundred yards to the south-east of Kensington Palace. A policeman informed me that he had killed it there last Thursday as it was rapidly moving over the ground. The head and neck had been utterly destroyed, most likely by stampings of the policeman's foot, but the remainder of the body was perfect. In length it was about twenty inches, the body, from the thickness of a little finger, gently tapering to a tail ending in a fine point. Regular scales, brownish-black in colour, clothed the back, the scales along the sides being yellowish-green. A distinct fringe, or prolonged fin, stiffly standing erect, of about one-quarter of an inch in height, ran down the centre of the back, in colour the same as the rest of the body in that region. I trust this description may enable some of your readers learned in snakes to identify the species. Then I would ask, Is this animal a native of these parts, or had it been introduced, or had this specimen most likely escaped from captivity to meet with its untimely end?

J. HARRIS STONE

11, Sheffield Gardens, Kensington, W.

THREE YEARS' EXPERIMENTING IN MENSURATIONAL SPECTROSCOPY

BY A NEW HAND THEREAT

IT was in 1876 that the experimenter,[1] of whom the following notes have been requested, clearly perceiving that it would not do any longer, even in his private work, to be content with merely a little direct-vision, ready-made, purchased, spectroscope and the few scale points offered by reference to lamp-flame lines—set about making up a tolerably large spectroscopic instrument to satisfy his own ideas, wants, and aims.

Now the leading desire with him herein, was, in suitable return for H.M. Government having then recently changed the locality of his official residence from a low, sunk position, where and whence little but other houses could be seen, to an elevated site half-way up the northern side of the Calton Hill, commanding an excellent view of the northern, north-eastern, and north-western horizons, together with the best and brightest parts of almost all auroral displays, whenever they occurred—it was his desire, as a decorous and appropriate tribute, to render some respectable spectroscopic account (over and above anything that the Royal Observatory, Edinburgh, and its more purely astronomical instruments could do) of those sometimes nocturnally luminous, but generally fitful, evanescent, and not yet fully explained, phenomena of the skies, the *Auroræ Polares*.

To this end the nascent spectroscope, mounted before a window in an upper chamber, assumed the form of a large flat telescopic box, almost five feet long, two broad, half a foot deep, supported on a stout alt-azimuth stand, with powerful screw motions. The box carried a gathering telescope in front, whose objective, as well as those of the internal collimator and inspecting telescope, were, like those of a "night-glass," large, *i.e.*, 2·2 inches in diameter; and short, *i.e.*, 17 inches, in focal length. An extensive and easily read scale for any prism's minimum deviation positions, and a long, but very easily worked, micrometer-screw motion for the telescope eye-piece were supplied, also an illuminated pointer. An electric reference spectrum of hydrogen lines above and below the fiducial central zone of the field of view was caused to be ever

[1] Prof. Piazzi Smyth, Astronomer-Royal for Scotland.

available; the slit, though 4 feet distant, was made capable of being adjusted from the observer's chair; a variety of prisms both simple and compound, with deviations from 0° to 45°, and dispersions from 0°·5 to 14° between A and H solar, but all of large size, and capable of being used in quick succession at pleasure, were added; with further arrangements for bringing into central view and correct measure, many other natural spectroscopic milestone lines, both with blowpipe-flame and induction-spark.

Thus far the instrument had been constructed, step by step to a series of orders, chiefly by M. Salleron, of 24, Rue Pavée au Marais, Paris, and it was ready in the beginning of 1877 for any aurora that should display itself in the north-north-western parts of the sky; but no auroras came, nor have any appeared up to the present time, February, 1880. But the instrument has not been idle. Its general material, wood, allowed it to be cut into and altered for any experiment, educational or otherwise; Mr. Adam Hilger, of 192, Tottenham Court Road, furnished it with a train of compound prisms raising its dispersion powers to 33° A to H, with improved Huyghenian rock-crystal eye-pieces and a spectrum-illuminated pointer of a remarkable kind for the purity of the colours successively imparted; until, though large parts of the apparatus were still rough, it had become, on the whole, an essentially *safe* instrument for spectroscoping numerically anything within its powers to spectroscope at all, and for looking into any such subject in a variety of different ways, and to different degrees as to definition, illumination, dispersion, and magnifying; thereby imparting considerable confidence in its final results: and this is the chief reason for saying so much at starting on the mere means employed.

Colours and Absorption Spectra.—The first series of observations with this new instrument was of a very simple kind as to the smallness of dispersion employed, and on an often discussed subject, viz., the colours both of the spectrum and of various coloured media, solid as well as fluid. These observations were printed by the Royal Society, Edinburgh, in vol. xxviii. of their *Transactions* (1878), in a paper extending through sixty-four pages and illustrated with three plates; one of them containing twenty-five different colours, viewed under seven different gradations. Though much of the subject matter of this paper could only be a confirmation, perhaps strengthening, of many previous workings by others in the same directions; yet the following points, more or less new, were also clearly established; as—

1. Colour bands, and bounding edges of coloured regions in the spectrum, are not fixed in spectral place as both Fraunhofer lines and luminous lines of gases so eminently are, but have a positive power of locomotion, within certain limits, according to intensity of illumination and depth of colouring matter. Witness especially the march of the whole red band of light, with successively increased depths of solution, over, and past, the black Fraunhofer line, both found on this occasion in oxalate of chromium and potash dissolved in water, and proved to be as fixed as any other Fraunhofer line in all spectroscopy.

2. Amongst colours the same to the eye, a physical difference still more important than colour was ascertained to exist, accordingly as their transmitted spectra formed, either one central beam, or two widely separated beams in spectral place. So that one *green* glass exhibited only the green region of the spectrum; while another glass, of different chemical coloration, but equally *green* to the eye, shone chiefly in setting forth the *ultra-red* regions of the spectrum at one end, and some of the blue at the other, but extinguished strangely the yellow, citron, green, and all that might have been expected *a priori* to have been well rendered by it.

3. Amongst these double-beam colours, of which cobalt-blue glass is an old example, well known from the times of Sir David Brewster downwards, a far more powerful case was met with in Judson's green dye of the aniline series; and by merely looking through a film of that (without any prismatic or spectroscopic assistance) it was shown to be possible to detect copper and arsenic greens among vegetable green dyes in papers and muslins; with all the facility too, of seeing the former become blue or black, while the latter became red, and sometimes gloriously so.

4. While the green of vegetation was in every case, both abroad and at home, together with its yellows, its blue as in litmus dye, and some of its browns, turned into crimson or scarlet—the green of shallow sea-water, as in the mouth of the Tagus, and the deep blue of the ocean, as in the Bay of Biscay, were both of them totally unaffected; but brown oars dipped in the act of rowing into the former, in itself unimpressible, green water, came up blood-red at every stroke; and brown sea-weed floating in the blue Bay, appeared of a richer scarlet than any coral. These scenes too were all the more brilliant and life-like to the observer, though looking through something like a black ink-bottle, from the tendency ascertained of two superposed films of any of these double-beam colours, when *differently* illuminated (the one looked *at* having to be more strongly illuminated than the one looked *through*), to produce light, rather than double dark, in and about the F region of the spectrum; thus recalling a remarkable feature established by the late esteemed Prof. Clerk Maxwell, in his researches on colour-blindness.

Rain-band Spectroscopy.—The next subject on which the experimenter published (both in the *Journal* of the Meteorological Society of Scotland and in the fourteenth volume of the "Edinburgh Astronomical Observations") was the power of the spectroscope to foretell rain. This subject had been much studied by him already in various countries and climates with pocket spectroscopes, but assumed a far firmer character when their indications could be tested by the spectroscopic machine above described.

Every spectroscopist knows how rich in black lines and grey bands is the red-end of the spectrum of the sky; especially towards sunset, and near the horizon. M. Ångström had moreover already taught that some of those lines or bands were due to watery vapour, and others to dry gas, in the earth's atmosphere; while M. Janssen had minutely identified the components of the former as being of such an origin, by comparing them with the absorption lines in a long tube of high-pressure steam. The Edinburgh experimenter therefore started with much prepared to his hand, when seeking to obtain a practical use for meteorology out of such observations; and his further steps were these:—

1. He ascertained by many months of continued daily experience that the lines attributed to watery vapour in the spectrum of the sky, though formed by that vapour when in the state of a transparent, invisible gas, increased in their intensity of darkness, other things being the same, according to the quantity of such vapour present in the atmosphere. That quantity being independently ascertained for the time by reference to wet and dry bulb thermometers and the usual hygrometrical calculations.

2. To keep those "other things the same," and prevent the variations they are only too capable of setting up, from interfering with the one phenomenon now sought after, the experimenter confined his spectroscopic notings of the sky's light to a constant, and that a low, altitude therein; as well as to an hour giving a constant, and not a very low altitude to the sun, and an azimuthal direction considerably distant therefrom. Also to blue sky itself, as seen through openings between clouds, if possible, rather than to any cloud surface, and much rather than to

any haze, fog, or smoke surface nearer still than the clouds.

3. These precautions being taken, there was no difficulty in recognising, *first*, during frosty weather, when meteorologists know there is a minimum of moisture in the air, what should be the normal appearance of the dry-gas lines or bands, for they only are then conspicuous, and are chiefly great B, the *alpha* band between C and D, and a remarkable band on the green side of the universally known D line of the regular solar spectrum. That band being remarkable, not only for being situated as a dark shade in the otherwise brightest part of the spectrum of daylight, but by being much more dependent than the other dry bands, on the lowness of altitude of the sun at the moment, for its full and darkest development, and thence called in these inquiries "the low-sun band." *Next*, in the summer season of the year when the temperature has risen say to 70°, and we know, as *per* the acknowledged hygrometrical tables, that there is then four times as much, to the eye invisible, moisture in the air, for that reason only, as at 30° temperature—spectroscopic observation will show, simultaneously with and in addition to, all the previous dry-gas lines, not only a strong water-gas, or vapour, line closely following C, a true sun-line, but a much grander line, double line, or rather band of lines immediately preceding the solar line D; and this particular water-vapour group is in practice the only one of that kind which meteorologists need attend to in their ordinary daily work.

So far indeed we have only got, by its means, a species of thermometer; but if we go on observing day after day in nearly similar summer temperature, and accustom ourselves thereby to the then quality of appearance of that band preceding D—and if on the next day, at the same, or nearly the same, temperature, we should see the band, say twice as dark as on the previous days—then in that excess of darkness it has become "the rain band" sought for. Because that abnormal excess of darkness shows as infallibly as though it were written up in the sky, that there is at that moment far more invisible watery vapour in the upper atmosphere than the air there is capable of holding much longer in suspension, wherefore such extra moisture must very shortly be deposited as rain.

This then is the "rain-band spectroscopy" established by the Edinburgh experimenter; and it may be now successfully practised with the smallest spectroscopes either at home or abroad; when one is travelling as well as when stationary, for it occupies only a moment of time each day, as the merest glance will tell whether the rain-band preceding D is much stronger or less strong than the normal quantity; and with all the more certainty on account of the low-sun band immediately following D in the spectrum, enabling a differential, as well as an absolute, estimate of darkness to be formed. While in any but very cold and wintry weather, when Nature herself tilts the balance for rainfall by a very small addition to the watery vapour in the air, the spectral indications are easily read off and apprehended. They have also been found as certain at sea, in South Africa, and India, or wherever the system has been carried, as in Great Britain during the best part of its summer season.

If the research be further prosecuted with large dispersions, high magnifying powers, and on the direct light of the sun, the hazy bands above spoken of as existing in the general daylight, are found in the same spectral places, but breaking up into scores and hundreds of fine lines; while the range of visible spectrum then extending from the B limit of the mere sky and indirect sun's light, to great A and beyond it—the intermediate groups of lines called "little *a* and its preliminary band" will be found a still more powerful "rain-band" than that near D. For though they, little *a* and its preceding band, are composed of lines vanishingly thin, few and far apart in dry weather and as seen in a high sky, yet their interstices in damp weather become peopled with myriads and myriads of black lines, so as at last, indeed, in a setting sun, to block up the whole space of each group, from one side to the other, solidly; and then actually to dwarf the almost proverbial spectral colossus "great A," into a mere line comparatively puny and unimportant.

The Red-End of the Solar Spectrum.—"There must surely be some mystery of difficulty," thought the experimenter, "touching the red-end of the spectrum of the high sun, or the able Ångström, of Upsala, would not have omitted it in his otherwise grandly perfect normal solar spectrum map; while some points in the Royal Society's Himalayan solar spectra would have been very differently rendered." Now one undoubted obstacle to mapping that part of the spectrum well, is undoubtedly the faintness of its light; wherefore an idea immediately occurred to the new worker that the qualities of his aurora spectroscope were the very desiderata for both the red, the ultra-red, and for everything, in fact, that the very beginning of the solar spectrum has to show beyond, or earlier than, the point where Ångström's spectrum commences its admirable delineations with the rudimentary lines of only little *a* and its preliminary band.

But the summer of 1877 threatening to be hopelessly cloudy in Scotland, the experimenter, after considering the various *pros* and *cons* of many southern stations, decided on trying Lisbon, as the place of all others giving the highest summer sun, the best climate, and most social facilities, with least time lost in getting there. And then he further happily experienced, not only that the magnificent steamers of the Pacific Steam Navigation Company of Liverpool, are the most admirable means of accomplishing the ocean transit; but that the directors of that Company are most favourably and liberally inclined to help on any really scientific matter when for the sake of science alone.

Hence it was that in June and July, in Portugal, with his Edinburgh spectroscope and a heliostat of simple construction worked for him by his Wife's hand and eye, the experimenter was enabled to see and map at noonday, and, day after day, in a high sky, free from ordinary telluric effects, all that portion of the solar spectrum outside, or situated preliminarily to, Ångström's shortened beginning; viz., the matchless series of lines that go towards forming the colossal groupings of both great A and its grand preliminary band; then beyond that the very strong line Y and the groups of finer lines on each side of it; and beyond that again, near the beginning of all *visible* spectral light, the strong line X, and certain thinner lines on either side of it.

Photography, as Capt. W. de W. Abney has admirably shown since then, can take account of many more lines still; and some of them so very far away beyond all *visible* red light, as to remind one of those other lines recorded by Dr. Draper, the elder, in his celebrated Daguerreotype spectrum taken in 1843, lines which are quite outside the pale of all optical spectra. But the human eye had probably never, up to 1877, seen more in the "red" than what the Edinburgh experimenter's roughly built-up aurora spectroscope showed on this occasion: and the whole result, as contributing at last the head-piece required for Ångström's normal solar spectrum, was described in the 14th volume of the "Edinburgh Astronomical Observations," published towards the end of the same year 1877. It was accompanied there by a map, extending from the beginning of all visible light, and including 62 lines up to the groups of little *a*, so correctly represented in themselves by the philosopher of Upsala.

(*To be continued.*)

EXPERIMENTAL RESEARCHES IN ELECTRICITY[1]

SUPPLEMENT TO PART III.—*The Electric Condition of the Terminals of a Vacuum-Tube after their connection with the Source of Electricity has been broken*

THE question has been mooted whether there is a polarisation of the terminals of a vacuum-tube after the discharge through it has been interrupted by breaking connection between it and the source of electricity. This question is to be understood in the sense—does there exist a *chemical* polarisation as is the case for instance with the terminals of a voltameter under similar circumstances?

The problem is by no means easy of solution. The authors believe, however, that the few experiments they describe, selected from a long series, will show that there is really no such polarisation of the terminals.

In the first instance the case of the voltameter is considered; the arrangement of the apparatus employed in the experiments is shown in Fig. 1, where K K′ represent

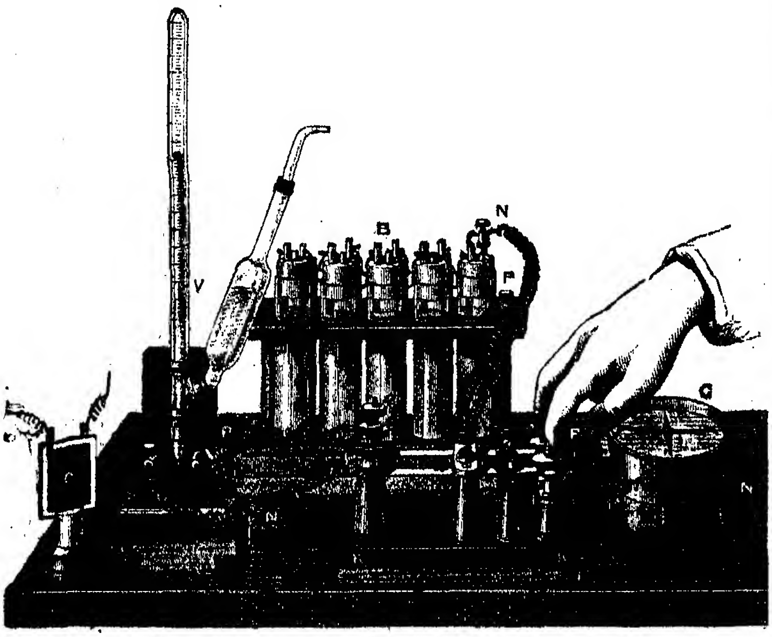

FIG. 1.

a special key for breaking connection between any piece of apparatus and the battery, B, and connecting it afterwards instantaneously with a galvanometer, G. The terminals of the battery are attached respectively to the screw-clamps, *c* and *d*, carried by an ebonite bar, supported on two ebonite columns, touch-points in metallic contact with *c* and *d*, pass through this bar, so that when the brass springs, *a c* and *b f*, are allowed to rise and press against these touch-points, the battery is in metallic connection with the screw-clamps, *a* and *b*, and any piece of apparatus attached to them, as, for example, the voltameter, V. The voltameter employed has a resistance of 20 ohms; its platinum electrodes are 2·5 inches long and 0·025 inch in diameter, and are separated 0·25 inch; it is charged with dilute pure sulphuric acid in the proportion of 1 volume of acid, sp. gr. 1·84, to 8 volumes of water. When the springs are suddenly pressed down by the fingers placed on the ebonite disks, *e* and *f*, the connection is broken between the voltameter and the battery, and it is connected instantaneously with the galvanometer G. The galvanometer actually employed was not that shown in the figure, but a Thomson galvanometer, whose constant,

$$C, = \frac{1 \text{ volt}}{1 \text{ megohm}} = 1{,}874 \text{ scale divisions.}$$

On connecting a battery of 10 chloride of silver cells with the voltameter for a minute or less, and then suddenly pressing down the springs *e* and *f*, there was a deflection to the left, say, of more than 1000 scale divisions, although the $\frac{1}{999}$ shunt was used to reduce the current through the galvanometer; therefore, the deflection without the shunt would have been more than 1,000,000 divisions. By comparing this deflection with that produced by a half microfarad condenser, charged with 240 cells, it was ascertained that the deviation produced by the voltameter was equivalent to that of 111 microfarads.

The small condenser shown at C, Fig. 1, was substituted for the voltameter; it is made of a thin plate of glass 2 inches square and 0·0115 inch thick; the tinfoil coatings being 1·5 inch square, its capacity was found to be 0·00055 m.f. When charged with 3,600 cells, and afterwards connected with the Thomson galvanometer through the $\frac{1}{9}$ shunt, by pressing down *e* and *f*, the deflection was 136·5 divisions to the left; this multiplied by 9·92, the value of the shunt was equivalent to 1,354 divisions.

The apparatus, shown in Fig. 2, which was constructed for another object already described,[1] was connected with *a* and *b*; it consists essentially of two disks, 3·1 inches diameter, placed 0·13 inch apart. The capacity of this apparatus, when used as an air-condenser, was determined, and found to be 0·000058 m.f. With 3,600 cells no discharge took place, and it merely charged up as a condenser. The deflection produced, when the keys *e* and *f* were pressed down, was (without shunt) 150 divisions, still to the left. It is evident, therefore, that the direction of the deviation throws no light on the question, for it is the same with the voltameter as with the condenser.

Tube 73, containing a residuum of acetylene, was now substituted for the air-condenser; it is 26·5 inches long and 1·5 inch diameter, the distance between the termals 23 inches; this tube was connected with 3,600 cells, current 0·00681 W The tube potential was found to be 2,980 cells, and its resistance 449,500 ohms. On pressing down the springs *e* and *f*, so as to break connection with the battery and connect the tube with the galvanometer, there was a deflection of 11 divisions to the left, the same as before. The current was only

$$\frac{11}{1874 \times 1{,}000{,}000} = \frac{1}{170{,}000{,}000} \text{ W.}$$

The diagram, Fig. 3, will illustrate the action of the special key, Fig. 1. When the handle is moved to the left, the tube T T′ is placed in metallic connection with the battery, whose terminals are shown attached to *c* and *d* (this is equivalent to the springs being allowed to press upwards against *c* and *d*, Fig. 1); when the handle is moved to the right, then the discharge of the battery through T T′ ceases, and the terminals of the tubes N and P are connected with the galvanometer, the extremities of whose coil are attached to *e* and *f* (this is equivalent to pressing down the springs in Fig. 1).

On another occasion with the same tube, No. 73, with

[1] "Experimental Researches on the Electric Discharge with the Chloride of Silver Battery," by Warren De La Rue, M.A., D.C.L., F.R.S., and Hugo W. Müller, Ph.D., F.R.S.

[1] *Phil. Trans.*, vol. clxxi. p. 76; NATURE, vol. xxii. p. 152.

a discharge from 2,400 cells, the deviation to the left on passing down *e* and *f* was 20 divisions.

Tube 199, with a hydrogen charge, was now substituted; pressure 2 millims., 2,632 **M**, 5,100 cells, current 0·01639 W. This tube has already been described (NATURE, vol. xxii. p. 176); it is 37 inches (94 centims.) long, and 5 13/16 inches (14·8 centims.) in diameter. The distance between the terminals, a ring and a straight wire, is 33·5 inches (85 centims.). In the first place the battery was connected direct to the galvanometer, the positive to *e* and the negative to *f* (that is, in the same direction as if the positive were attached to *c* and the negative to *d*). A short piece of wire was inserted between *e* and *f* as a shunt, and the 1/99 shunt was also used with the galvanometer, the direction of deviation was found to be to left, which it was desired to know.

On pressing down *e* and *f*, the deviation was to the left, and only amounted to 2 divisions. On another occasion, at the same pressure, 3,900 cells, current 0·02925 W., the deviation to the left on pressing down *e* and *f* was from 3 to 5 divisions.

The same tube, with a charge of coal-gas, pressure 3 millims., 3,947 **M**, current 0·01705 W., deflection, on pressing down *e* and *f*, 7 divisions to left.

The same tube, with air, pressure 1·5 millims., 1,974 **M**, current 0·02728 W., on pressing down *e* and *f*, deviation 20 divisions. The deviation was, therefore, greatest with air; but if due to a chemical polarisation, it would have been *a priori* expected to be greatest with coal-gas, which is a mixture of decomposable molecules. The result of the experiments with tube 199 gave the following deviations:—

Hydrogen.	Coal-gas.	Air.
3	7	20

Again, tube 199, 2,400 cells, pressure 1 millim., 1,316 **M**, current 0·02456 W., deflection on pressing down the keys, 16 to left; with 1,500 cells no discharge, yet a deflection of 10 divisions to the left was produced on pressing down the keys. The deflection in the latter case being clearly due to a static charge.

Experiments were now made in air with an apparatus similar to that already described in NATURE, vol. xxii. p. 174, but with disks instead of points, in order

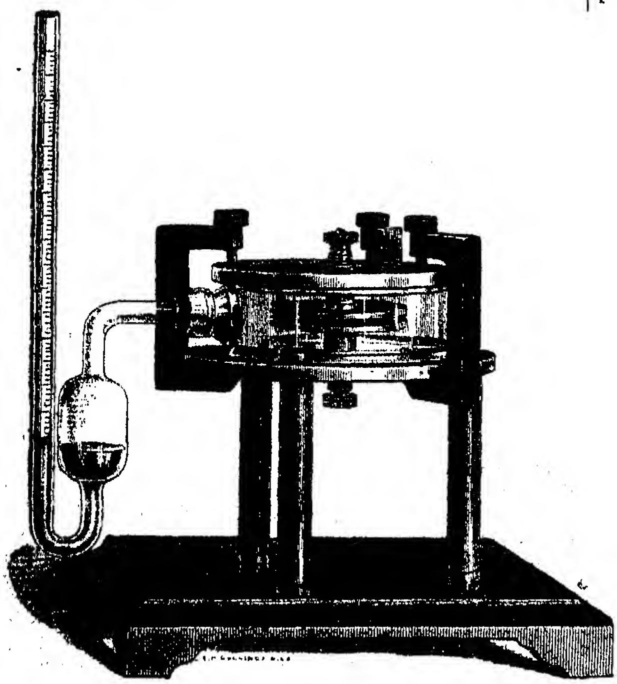

FIG. 2.

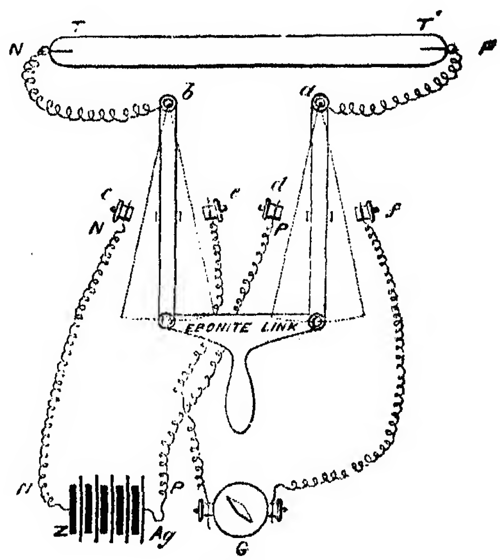

FIG. 3.

to obtain a vacuum vessel with large terminals. The terminals are two disks a little over 4¼ inches (11 centims.) in diameter, and in the first instance were placed 3 inches (7·62 centims.) apart. Pressure 4·5 millims., 5,921 **M**, 2,400 cells, current 0·04366 W., deviation on connecting the disks with the galvanometer, 10 divisions to left.

With 1,200 cells, no discharge took place, but on connecting the galvanometer a deviation of 27 divisions to the left was, nevertheless, produced.

At a pressure of 20 millims., 26,316 **M**, with 3,900 cells, no current passed, but the deviation on connecting the galvanometer, was 66·6 divisions to the left.

The disks were now placed at a distance of 2 inches (5·08 centims.), the pressure being still 20 millims., and the battery 3,900 cells, the discharge now took place, current 0·03896 W., deflection on connecting galvanometer 8·5 to left.

On reducing the battery to 2,400 cells, the discharge did not take place, but a deviation of 43 divisions was produced on pressing down *e* and *f*.

The disks were placed at 1 inch (2·54 centims.) apart, same pressure, with 3,900 cells, the current was 0·04201 W., deviation to left on connecting the galvanometer 13 divisions.

2,400 cells would not pass, but a deviation to the left of 47 divisions was obtained on connecting the galvanometer.

The following are the results of these experiments with the disks at various distances:—

Distance, inches.	No. of cells.	Pressure. mm.	Current.	Deflection on connecting galvanometer, divisions.
3	1,200	4·5	did not pass	27·0
3	2,400	4·5	passed	10·0
3	3,900	20·0	did not	66·6
2	3,900	20·0	passed	8·5
2	2,400	20·0	did not pass	43·0
1	3,900	20·0	passed	13·0
1	2,400	20·0	did not pass	47·0

So that in every case when the current had not passed

the deflection was the greatest on connecting the terminals with the galvanometer.

If the fact already pointed out be taken into account, that with a constant battery-potential, the difference of potential between the terminals of a vacuum-tube varies, in the same gas, according to the degree of exhaustion, it follows that as soon as a discharge takes place, the potential of the terminals will be lowered. One would therefore expect to find what the before-cited experiments indicated, namely, that the static charge of the terminals would be greater when no discharge takes place than after it has occurred, notwithstanding that a larger number of cells may have been employed in the latter case than in the former, for the authors have shown (*Phil. Trans.*, vol. clxxi. p. 67) that a tube-potential may be only 430 cells, although the battery connected with its terminals is 11,000 cells.

The authors believe, therefore, that the experiments point conclusively to the deduction that the current obtained from the terminals of a vacuum tube, after having been disconnected from the battery, is solely due to a static charge and *not* to a *chemical* polarisation.

An experiment was made with the apparatus arranged as in Fig. 4, a tangent galvanometer being inserted in the

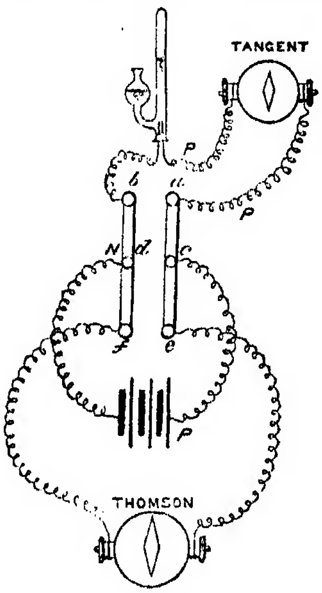

FIG. 4.

circuit between the battery and the voltameter, the $\frac{1}{999}$ shunt being used with the Thomson galvanometer.

No. of cells.		Current indicated by the tangent galvanometer. W.		Deflection of Thomson galvanometer, with shunt $\frac{1}{999}$, on pressing down *e* and *f*.			Divisions.

so that it was evident that a current was kept up by the voltameter for a considerable time after the battery had been disconnected.

In order to render evident the direction of the current of polarisation of the voltameter the apparatus was arranged as in Fig. 5, that is, the Thomson galvanometer, with $\frac{1}{999}$ shunt, was inserted in the circuit between the battery and the voltameter. An adjustable shunt was fixed between *a* and *b* to permit the greater part of the current to pass through it. A plate of metal, *s s*, was provided to slip under *e* and *f* to short circuit the return current through the galvanometer. The shunt which was found just sufficient to carry the major part of the current, and yet permit sufficient to traverse the voltameter to produce a just visible evolution of gas, was 13 ohms.

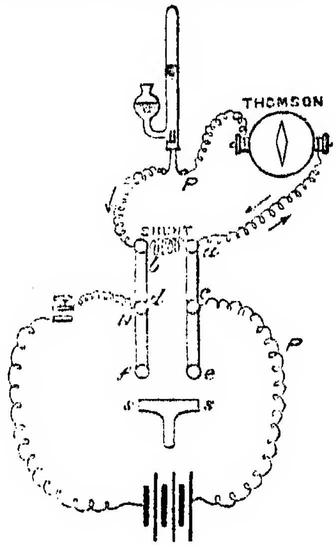

FIG. 5.

On connecting the battery, the current was in the direction of the lower arrow, and the deviation 133 divisions say to the left; on pressing down the keys on to the metal slip placed under them to short circuit the current, after the battery had been disconnected, the return current was in the reverse direction, as shown by the upper dotted arrow, the deviation being 425 divisions to the right. Even without pressing down the keys on to the metal slip nearly the same deviation was obtained on disconnecting battery for the return current then traversed the shunt from *a* to *b*.

On substituting either the bell-jar, with disk terminals, or the tube 199 for the voltameter, the deflection of the return static charge was in the same direction as the return current from the voltameter, so that, as was before stated, no inference can be drawn from the direction of the current as to its being produced by polarisation or a static charge. The authors conclude by saying:—We think, however, that we have shown that the effect in the case of a vacuum-tube is due to a static charge, and not to a polarisation of the terminals. We rest our opinion mainly on the fact that a greater deflection is produced, when the potential has not been lessened by a discharge through the tube, than that which occurs after the discharge has taken place, which, it had been surmised, might possibly produce a chemical polarisation.

THE LATE M. GAUGAIN

SCIENCE has to deplore the loss of an industrious but unobtrusive worker in the person of Jean-Mothée Gaugain, who died at the village of St. Martin d'Estreaux,

near Bayeux, on the 31st of May, 1880. His name is honourably associated with experimental researches in a good many of the less-frequented bye-paths of electrical science. Living in a time which may well be regarded as the transition period, during which electricity has passed from the stage of a phenomenal and experimental science to one of exact mathematical relations, some of Gaugain's investigations are already superseded by the later and more comprehensive researches of a younger generation. Yet he has done good work, which will live to carry down his name along with that of Peltier, of Pouillet, and of Becquerel, and with the still greater names of Arago and of Ampère.

His earliest contribution to science of which we are aware was a memoir published in 1853, under the title "Note sur les Signes Electriques attribuées au Mouvement de la Chaleur," and in the same year he brought out his tangent galvanometer. The essential point of this instrument consisted in employing as a coil several turns of wire of increasing diameter arranged about a conical surface, at whose imaginary apex was placed the small magnetic needle, each of the coils thus subtending the same solid angle at this point. This arrangement, to which Gaugain was experimentally led, was in some points virtually anticipated by the tangent galvanometer of Helmholtz, in which, however, a symmetrical arrangement was employed. In the same year Gaugain announced the discovery that continuous currents of electricity could be produced by the continuous friction of two dissimilar metals upon one another. The next two years saw him employed in investigating the electricity produced by evaporation and by combustion. In 1856 he produced his double-condenser electroscope, designed, like the condensing-electroscope of Volta, for the investigation of the electrification due to contact of dissimilar substances. At the same time he published some observations on the behaviour of amalgams of sundry metals, and showed that in a voltaic pair the amalgam of zinc was more electro-positive than zinc itself, while the amalgam of cadmium was on the other hand, more electro-negative than the pure metal. From 1856 to 1859 Gaugain was occupied with important inquiries on pyroelectricity, and he succeeded in establishing sundry laws, with respect to the electricity of the tourmaline in particular, which had escaped previous observers. The results he arrived at were published in the *Annales de Chimie et de Physique*, and comprised a number of curious and unexpected results. The tourmaline, which at ordinary temperatures is a bad conductor, even for high-tension electricity, begins to conduct at 400° or 500° C., and on cooling is still found to conduct; but if washed in water and dried carefully it once more insulates. All tourmalines are not equally active, those of Brazil, green or blue in colour, being the most electrical. In order to obtain a measure of the amount of electricity furnished by a tourmaline whose poles were united by a metallic circuit, he devised a discharging gold-leaf electroscope, and by means of this instrument showed that a number of tourmalines united by their similar poles gave quantities of electricity proportional to their number, while if united in single series they gave no more than a single long one, thus behaving like batteries of great electromotive force and of almost infinite internal resistance. The quantities of electricity furnished by tourmalines of equal lengths but of different thickness while passing through equal ranges of temperature he found to be proportional to the cross-sections of the crystals, again agreeing with the law of Ohm as applied to batteries of very high internal resistance. Gaugain also showed the quantity of electricity thus flowing through the tourmaline in one direction during a rise of temperature to be equal to that flowing in the reverse direction during a corresponding fall. The year following the discharging electroscope was usefully employed in verifying Ohm's law as applied to other bad conductors. Volta's contact theory occupied Gaugain at several periods of his career, and he established amongst other interesting results that there is a difference of potential between a piece of platinum which has been dipped into acid, and one which has been dipped into alkali, even though both have been subsequently washed. Gaugain also conducted a number of careful researches on specific inductive capacity, on the capacity of cables, on the residual charge of condensers, and on what he termed the variable electric state of a condenser communicating with the soil by a bad conductor, in which, when discharged by disruptive sparks or by the discharging electroscope, the time-intervals of the discharges were found to form a geometric progression. His extended observations on condensers of spherical, cylindrical, and flat forms were communicated to the Académie des Sciences in three special notes. In later years Gaugain devoted himself to the examination of the effects of heat upon the magnetism of steel tubes and bars, and found the remarkable result that a bar magnetised powerfully while hot may when cooled exhibit a reversed polarity, and *vice versâ*; also that the magnetisation by a strong current penetrates deeper than that due to a weaker current. He also brought to light sundry analogies between the behaviour of magnets under magnetic force, and of matter generally under mechanical forces.

Born in Normandy in 1810, he entered the École Polytechnique at about the age of eighteen, and afterwards attended the École d'Artillerie at Metz, after which he adopted metallurgy as his profession. Gaugain worked during the closing years of his life in isolation and in straitened circumstances, assisted by his only daughter, who devoted herself to him. His researches, though several times rewarded with academic recognition, were not in themselves productive of gain; and the *prix Gegner*, an annual grant of 4,000 francs, given *à un savant pauvre afin de l'aider dans ses recherches*, awarded to him for five years past, was a welcome amelioration of his position in a time of failing health and during the painful illness to which he succumbed at the age of seventy years.

S. P. T.

A CHAPTER IN THE HISTORY OF THE CONIFERÆ

IN working out the Eocene coniferæ, in continuance of the monograph which the Palæontographical Society are kindly publishing and illustrating in a sumptuous manner, some reflections upon the past history of the more prominent Eocene genera, such as Araucaria, Podocarpus, Dammara, Sequoia, &c., have occurred to me, which, although being perhaps outside the scope of the Palæontographical Society's work, may not be uninteresting to the general readers of NATURE. I have therefore tentatively brought forward the present chapter on Araucarias without yet having any definite intention of putting together my notes upon the other genera, in the present form.

Araucaria,[1] Jussieu.—The earliest traces of distinctly coniferous wood known, those from the Carboniferous, were for many years thought to belong exclusively to the Araucarian type. This supposed prototype became, according to Schimper, modified in successive ages, and he endeavours to trace these modifications through the extinct genera Walchia, Ullmannia, Araucarites, Voltzia, Ptycholepis, Pachyphyllum, and Cunninghamites. Lesquereux, however, carries the actual genus Araucaria to as far back as the Trias, and unmistakable cones of both sections of the genus have been described by Carruthers from the Stonesfield, Yorkshire, and Somersetshire oolites; fossil forms agreeing closely with these have been also found in the Jurassic of India. It is not

[1] From Araucanos, a people of Chili, in which country *A. imbricata* abounds, and furnishes the principal food of the Indians.

definitely known at present in cretaceous rocks, for the large fossil cone figured by Heer as *Araucarites nordenskiöldi*, from the upper cretaceous of Spitzbergen, is a very indistinct coaly mass, and as he suggests, possibly cycadaceous.[1]

The Araucarias thus appeared to have declined since Jurassic times, and Schimper states that, with the Tertiaries, they became extinct in Europe. Thiselton Dyer[2] goes further, and has even stated that, so far as we know, they have been extinct north of the equator since the Oolitic age. It is certain, however, as I hope to show, that at least one section of them abounded in Europe during the Eocene age, and probably did not quit it until the Miocene.

The existing Araucarias present a singular appearance when contrasted with other trees, and would be looked upon from their aspect alone as unmistakably archaic in character. They have been divided by Salisbury[3] into two very distinct sections: Columbea, or true Araucarias, and Eutacta, or the needle-leaved false Araucarias. They are exclusively confined to the southern hemisphere, Columbea alone being represented in South America, and both sections in Australia and the adjacent isles.

The section *Columbea* possesses but four species, which are, however, very distinct from each other and of great interest. The most familiar is the common *Araucaria imbricata*, or Monkey-puzzle. It is almost confined to Chili, forming vast forests which extend upon the slopes of the Andes from the snow-level to about 1,500 or 2,000 feet downwards. The trees reach 150 feet in height, and with their dark pendulous foliage are of imposing grandeur. Their appearance when full grown can scarcely be realised from the young trees in England, but an exceptionally fine specimen is at Windsor, and a carriage-drive leading to a nobleman's house, near Armagh if I remember rightly, is bordered by high banks of large and, for our country, well-grown trees of this species, and presents a strikingly dignified effect. The cones are very large, and the seeds, which are highly nutritious, form the staple food of the Indians. The second South American species, *A. brasiliensis*, is somewhat similar in appearance, and reaches 100 feet in height. It also forms immense forests, and produces edible nuts, but as it will not live in our climate without protection, is less frequently seen in cultivation.

The Australian species are even more strange in aspect. *Araucaria Bidwillii* forms a majestic tree, growing to 150 feet in height, and confined to a tract 30 miles long by 12 on the east coast near Brisbane, where it far overtops the other forest trees. *A. Rulei*, a smaller though equally beautiful tree, is chiefly remarkable for its singularly restricted range, being only indigenous to Porte Molle, one of the Caledonian Isles, where it is confined to the summit of an extinct volcano, but half a mile in radius, and exposed to extremes of heat and cold that appear destructive to other kinds of vegetation, for hundreds of feet below it.

The Columbeas have not been met with fossil either in the Eocene or Cretaceous rocks, probably because their stations are mostly high rocky ridges, where there is an absence of water, rendering it unlikely that their remains would find their way into marine or fluviatile sedimentary strata. We must by no means infer, therefore, that species belonging to this section did not exist in Europe contemporaneously with the species of Eutacta that have been found.

The section *Eutacta* has terminal globular cones with broadly-winged and generally persistent scales and falcate needle-like leaves. There are but three existing species, all of gigantic dimensions, for two of them attain a height of over 200 feet, and the third 150 feet. *Araucaria Cookii*, or the Norfolk Island pine, a native of New Caledonia and New Hebrides, presents a fantastic columnar-like growth, giving the trees when seen from a distance somewhat the appearance of a grove of ship's spars 200 feet or so in height. *A. excelsa*, indigenous to Australia and Norfolk Island, is an even more majestic and colossal tree, towering to a height of 230 feet, with a trunk of some 30 feet in girth. The third species, *A. Cunninghami*, I wish to describe in more detail, for I have ascertained, conclusively I believe, that it, or a species indistinguishable from it, flourished abundantly in our latitude and longitude in the Middle Eocene period.

A. Cunninghami, like many Coniferæ of the southern hemisphere, has two slightly distinct forms of leaf, those of the young plants being straighter, more sabre-like, and horizontally disposed than those of the more fully developed tree, which hitherto have alone been met with fossil.

The foliage of the more full-grown tree is composed of moderately short falcate needle-like leaves, quadrangular in section, thickening at the base, and with the lower side produced and decurrent on the stem. These are disposed all round the branches, and leave the stem at first at right angles to it, and then gently curve upward and inward. This arrangement causes each leaflet to be free or seldom in contact one with another, and is an important character in distinguishing the species by its foliage when other organs are absent. The terminal branchlets are generally simple for 5 or 6 inches, and then branch shortly but copiously, and chiefly horizontally. These branchlets apparently represent one year's growth, for they are articulated at the base, and are annually shed in abundance by the trees. Branchlets resembling these in the minutest particulars are to be found in great quantities in the Eocene beds at Bournemouth.

Other coniferous foliage, however, resembles *A. Cunninghami*, especially that of some of the cultivated *Sequoia gigantea*, so much so that I had difficulty in removing the prejudice from Ettingshausen's mind, shared by all the Teutonic palæobotanists, in favour of referring all this type of foliage to Sequoia. Before it can definitely be said to belong to *A. Cunninghami* these types of foliage must of course be considered.

In the first place the foliage of *A. Cunninghami* is easily distinguishable from that of the other Araucarias in the section; *A. excelsa* having leaves more at right angles, more laterally disposed, and foliage less branching, and *A. Cookii* possessing the leaves broader and in contact with an imbricated appearance, while every articulated branch is simple. The other Coniferæ which resemble it are *Cryptomeria japonica*, in which the leaves are much longer and straighter, and quit the stem at an angle of about 35°; *Arthrotaxis selaginoides* and *Dacrydium araucaroides*, which have the imbricated appearance of *A. Cookii*; and *Sequoia gigantea*, which is much the nearest in general habit. The leaves of Sequoia differ in being rather longer in proportion, less regularly disposed and curved, leaving the stem at a very acute angle, and hugging it more closely, so that their points irregularly overlap and touch each other. Its foliage in the wild state seems always to be very much smaller, and the larger foliage it seems sometimes to assume away from its native habitat, shows very distinctly the seasonal variations in the size of the leaves so characteristic in the other existing Sequoia, *S. sempervirens*. The Bournemouth foliage differs from all these materially, but as already stated, resembles that of *Araucaria Cunninghami* in so close a degree as to be indistinguishable from it by any discoverable character.

Apart from the foliage, however, there is other evidence in support of the view that this is really *Araucaria*

[1] "Flora foss. Arctica," vol. iii. Pl. xxxvii. p. 126. Heer says the figure is much too distinct, and that the position and arrangement of the scales can only be made out with the greatest trouble. Restored as it is, it possesses no distinctively Araucarian characters, while no branches of Araucaria have been found that could be placed with it. Cycadaceous and Sequoia foliage moreover abounds in most cretaceous rocks in high latitudes.

[2] Royal Geog. Soc. *Proceedings*, 1878, vol. xxii. p. 427.

[3] *Trans. Linn. Soc.*, vol. viii., 1807, pp. 308-317.

Cunninghami. Although the branchlets are most abundant in some of the beds, both marine and freshwater, no trace whatever of the cones could be found. I was at first surprised at this, for it is generally more common in beds of marine origin, as at Bracklesham, Barton, Sheppey, &c., to meet with cones than with foliage, and no instance of the presence of coniferous foliage only, in a sea-deposit of any age had previously come under my notice. I was so puzzled that I spent several days in digging and tracing out these branchlets and vainly trying to find the attached fruits—the cause of whose absence should have been clear. The cones, 3 inches long and nearly 9 inches in diameter, are so exceedingly dense and heavy that they have no power of flotation, and their presence in beds of fine drifted sediment could therefore only be due to some rare accident. On the other hand, the small light cones of Sequoia would, like those of Pinus, everywhere drift by flotation, and necessarily not unfrequently become imbedded with the foliage. Although I found no cones, the female terminal buds present the peculiar constriction and then swelling, so characteristic of Araucaria.

The distribution of *Araucaria Cunninghami* at Bournemouth is very clearly defined, and tells as plainly as possible that its habits when existing in our latitudes did not differ from those it now possesses. No trace of it is met with west of the pier in the beds whose floras may be thought, from their characters, to have come from districts away from the sea—but east of the pier it abounds everywhere, in company with fan-palms, eucalyptus, aroids, ferns, &c., and in certain beds of mud and muddy sand of the marine series, the branchlets, in marvellous preservation, are seen to cross each other in every direction.

The existing *Araucaria Cunninghami* forms vast forests on the shores of Moreton Bay, on the alluvial banks of the Brisbane River, and grows in the greatest profusion in the brush forests of the Richmond River. "The trees seem to thrive best near the coast, attaining in such a situation their greatest height, often from 100 to 130 feet,[1] but gradually diminishing in height the farther the trees are inland. It would appear from this that the sea air has a great effect upon it."

The "brush" forests, in which *A. Cunninghami* very generally occurs, although it is not exclusively confined to them, are thus described by Moore:—

"The 'brush' is characterised by denseness of growth, the altitude and beautiful dark green foliage of the trees, the presence of lofty climbing plants, which extend their slender pliant branches considerable distances, and by this means often embracing, as it were, into one common bond, many of the loftiest and largest trees. . . . Another characteristic of forests of this description is a thick undergrowth of numerous kinds of ferns and other plants. Palms and tree-ferns also usually abound, the former reaching a height, in some instances, of at least 130 feet. . . . On the stems and branches of the trees numerous kinds of epiphytal ferns and orchids grow, which, with the other plants referred to, contribute materially to give such forests a very tropical appearance."[2]

It is clear, from the *débris* of trailing Smilaceæ and Aroids, and from the remains of large fan-palms and ferns, that our Eocene "brush"-growth must have been very similar to this in appearance. The physical aspects of the former stations of Araucaria on the alluvial banks of the great Bournemouth River in close proximity to the sea, as we have ascertained, and its probable extension along the shores of what must have been the *east coast* of the submerged continent seem to approximate to those it now occupies on the Brisbane River and the shores of Moreton Bay on the east coast of Australia. Nothing can be more impressive indeed than the remarkable agreement in habit, as far as we can trace, between the Araucaria and associated plants that have passed away and those that survive. The long-imbedded plants of our Eocene coasts seem to have risen up and to live again in this far-off country, and by what we see there we are able to picture the long sandy coasts, beaten by an ocean surf and fringed with dark-foliaged and gigantic Araucarias, gum-trees, luxuriant palms and ferns, whose remains have helped to form the present pine and heather-clad cliffs of Bournemouth. If we contrast this with the comparative absence of any associated vegetation in the Mammoth Grove, we see how opposed the intended reference of these branches to Sequoia would have been to any known natural grouping.

Elsewhere in Great Britain we have little trace of anything referable to Araucaria younger than in the Jurassics, except certain foliage at Sheppey and the foliage from the basalt of Antrim, referred by Bailey to Sequoia as *S. du Noyeri*, about which however I am not yet able to express an opinion. In France, from many Eocene localities, undoubted Araucaria branches have been obtained, though none of them seem to be specifically identical with ours, and some appear more of the *A. excelsa* type.

In Central Europe, from Sotzka, Häring, Monte Promina, Bilin, &c., in Tertiary beds whose exact age is not yet satisfactorily determined, a somewhat similar foliage abounds. This was originally described as Araucarites, and indeed at Häring a young cone with every characteristic of Araucaria was found in the same bed with it.[1] All of them were subsequently transferred to Sequoia, which many certainly more nearly resemble in the direction and arrangement of the leaves; yet the absence of any Sequoia cones which can, so far as I know, be directly connected with them, and the presence of a characteristic Araucaria cone should, at all events, induce caution in believing the whole of this type of foliage met with in Central Europe during the Middle or Upper Eocene to belong to an ally of *Sequoia gigantea*. It is quite open to doubt whether, as Heer's determination of two fragments would imply, this species known as *S. sternbergeri*, whatever its real character may be, persisted as late as the Miocene of Oeningen. On the other hand, the presence of fossil Sequoiæ of the Wellingtonia type within the Arctic circle is undoubted, though Heer appears to have made more species than were necessary.

The presence of an Araucaria, indistinguishable from *A. Cunninghami*, in our latitudes at a time not more remote than the Middle Eocene, is of interest, for although many of our Eocene plants have been referred to Australian genera, there has always been doubt sufficient to render any confirmation of the supposed land connection with Australia of importance. While the association with it at Bournemouth, of Podocarps and Dammara, Eucalyptus, and many Proteaceæ, which are strictly forms of the southern hemisphere, is but natural, the presence of a needle-leaved conifer of the genus Pinus, even rare as it is, is singular. Such a union nowhere takes place at the present day, although in Mexico pines mingle with feather palms.

The presence in N. lat. 50° of a flora, now distinctive of the sub-tropics of the southern hemisphere, and of a north temperate flora in N. lat. 70°, during the Eocene period, can hardly fail to provoke wonder as to where the equator of heat was then situated. It is impossible to suppose that the equator of heat separated them as it does now, however far north it might be driven by shutting off the Arctic currents and leaving those of the Antarctic to circulate. Yet if the southern hemisphere flora were formerly to the north of the equatorial zone of heat, the question must arise as to how *Araucaria Cunninghami*,

[1] 130 feet. "Industrial Progress of New South Wales: Official Report of the Sydney Exhibition, 1870," Part II. p. 643. It is astonishing how very generally the dimensions of the Coniferæ of Australia and America are under estimated.

[2] *Loc. cit.*, p. 633.

[1] "Foss. Coniferæ," Goeppert, Haarlem *Transactions*, 1850, pl. 44, p. 237.

and other forms that are not tropical, could have reached their present habitat. The range of this Araucaria, although greater by far than that of the other Eutactas, is very definitely limited to a strip of coast in New South Wales between the Bellingen, a small stream about S. lat. 31° 40′, and Cape York in Queensland, in nearly 10° S. lat. It does not approach, therefore, to within nearly a thousand miles of the equator of heat, which is several degrees north of the true equator. They must either have crossed the equator from the south in præ-eocene times and subsequently become isolated and died out in their northern habitat, or have been originally indigenous to the north and retreated to their present stations. A passage must have been made in either case, for the present distribution of Coniferæ is against the supposition that any *identical species* could have extended synchronously in lowlands in both hemispheres, widely separated by the equator. If a general lowering of temperature had favoured their passage, the pre-existing tropical vegetation must have altogether died out, and the existing equatorial vegetation would present a comparatively new aspect. The absence of any of the Coniferæ that have ever been met with fossil in the plains of the tropical regions at the present day, and of any existing strictly equatorial plants, such as Gneta among Conifers, in the fossil floras, seems at first sight to show that it does do so and therefore lends some colour to what is at best merely a very crude hypothesis. A simpler supposition than that of a general lowering of temperature in the Tropics, until more facts are forthcoming, is that the passage was effected across high land, some of which may still remain in Sumatra and Java.

The specific identity which is apparent, of this and other Australian forms, with those of our Eocenes, proves that some, at all events, of the at present purely Australian genera, neither originated nor became differentiated, as Bentham supposed, in Australia. The endemic genera, he says, never spread far out of it, the only exceptions appearing in the Malay Archipelago, "especially Timor, New Guinea, and Borneo, and a few as far as Southern China."[1] Nothing could speak more eloquently of the path the migrations have taken, than these remnants left upon the road, nor go farther to prove the former connection with our antipodes, which the discovery in 1814 by Brown of 150 European plants, a number since greatly increased, growing endemically in Australia, first of all I believe suggested to us.

It may not be altogether a useless supposition to hazard, that if, as Saporta supposes, plants originated mainly if not wholly in northern regions, and migrated south, the continents of the southern hemisphere may be actually preserving, as in the present case, our Eocene flora, and have been inhabited in Eocene times by the Jurassic flora which preceded it, or by some intervening flora of which we have now but the scantiest records.

From what has been said the Araucarias are seen to be an archaic type, formerly most widely spread, now dying out and only lingering in restricted areas in the southern hemisphere, whose very specific differentiation was accomplished before the Eocenes began. May its value as food and use as the chief timber tree in the districts it still inhabits preserve it from an accelerated extermination at the hands of man.

J. STARKIE GARDNER

[1] Bentham, "Flora Australiensis," vol. vii.

ON SOME POINTS CONNECTED WITH TERRESTRIAL MAGNETISM

THE remarks in NATURE, vol. xxii. p. 169, of Messrs. De La Rue and Müller in connection with their most interesting and important researches on rarefied gases induce me to ask the privilege of stating somewhat more fully than I did on June 17 what I conceive to be the position filled by a working hypothesis such as that then mentioned in the science of terrestrial magnetism. Let me begin with the aurora. Here we have a phenomenon which invariably accompanies magnetic storms, on which occasions it occurs simultaneously over a large portion of the globe. Again the recent researches of the above-named gentlemen render it very probable that auroral displays do not occur at a very great height, while it is conceivable that they may occur at times at an altitude of a few thousand feet. Here then we have a phenomenon which is intimately connected with sudden changes of the earth's magnetism. To this we may add earth currents as another phenomenon of the same kind, so that we have earth currents and auroral displays invariably associated with magnetic storms, when these are of marked violence. Now what is the nature of this connection? When we examine the formal laws of these associated phenomena we find that these lead us (almost irresistibly, as I think) to conclude that earth currents and auroræ are secondary discharges caused by sudden changes in the earth's magnetism, no matter how these changes are produced. So strong is the evidence of *form* in this instance that the late eminent magnetician John Allan Broun expressed to me his belief that earth currents and auroræ were connected with magnetic storms in the way above mentioned.

If this be assumed as the most probable working hypothesis, it is natural to take another step. If we have discharges produced in stationary strata by a changing magnet, may we not have discharges produced in moving strata by a constant magnet, and may not the motions and changes of motion produced by the sun in the upper convection currents of the earth give rise to electric phenomena which may explain the changes of terrestrial magnetism? Of course this is only a working hypothesis. Before it can possibly become an established theory we must have obtained from Messrs. De la Rue and Müller and from other observers that full and complete information regarding discharges in rarefied media which they are rapidly affording us, and we must likewise have obtained fuller information than we now possess regarding the directions and velocities of the convection currents in the upper regions of the earth's atmosphere. When this is done, the problem may be regarded as ripe for the mathematical physicist who may proceed with his calculations and either dismiss the hypothesis as untenable or increase the probability of its truth.

But in the meantime we are not ripe for this, and all that we can do is to regard the hypothesis as a working one, and endeavour by its means to elicit new facts regarding the *form* of the diurnal and other variations of terrestrial magnetism. I submit that in this respect the hypothesis has not been devoid of value. I have by its means been led to derive the fact that certain magnetic diurnal changes lag behind corresponding solar changes, just as meteorological changes would do—a fact which has since been confirmed by Mr. Ellis of the Greenwich Observatory. And I may be allowed to anticipate the results of work at which I am now engaged so far as to say that in the short periods which I am now investigating an increase or decrease of solar activity corresponds to an increase or decrease both of magnetical and meteorological activity.

Again, in conjunction with others, I have shown by preliminary discussions the probability of a progress of magnetic phenomena from west to east just as we know there is a progress of meteorological phenomena, only magnetic weather (if I may use the expression) appears to travel faster than meteorological weather. This last appears to me to furnish almost a crucial test in favour of this hypothesis, and through the courtesy of the Kew Committee, the Astronomer Royal, and Mr. Carpmael of Toronto I hope to be able soon to investigate this phenomenon in a more complete manner.

Finally, I understand that the Kew Committee are about to take in hand the subject of the progress of magnetic weather and to investigate it in a manner peculiarly suitable to an institution possessing relations with numerous self-recording magnetic observatories.

BALFOUR STEWART

NOTES

THE fund which has been established by the members of the Birmingham Philosophical Society for the endowment of original research already amounts to 700*l.* in donations, and to 70*l.* in annual subscriptions. Out of this a sum of 150*l.* per annum for three years has been voted to Dr. George Gore, F.R.S., which amount is, in the terms of the grant, placed at his disposal in order that he "may have greater facilities for continuing in Birmingham his original researches." The council of the society proposes to make other grants as soon as the funds will permit. We have already spoken of the enterprise and public spirit of this society in establishing the fund; it is gratifying that they have been able to make a beginning so speedily, and the success of the scheme cannot be doubted. Dr. Gore's address is now the Institute of Scientific Research, No. 67, Broad Street, Birmingham.

WE are glad to hear that Mr. L. Fletcher, M.A., Fellow of University College, Oxford, has been appointed to succeed Prof. Story-Maskelyne as keeper of the Mineral Department of the British Museum. Mr. Fletcher was appointed first assistant in the department a little over three years ago, and the energy and ability with which he discharged the duties of that appointment promise well for the future of the Mineral Department.

WE regret to have to announce the death of Mr. Henry Ludlam, which occurred last week from the rupture of a blood-vessel. He had been in failing health for some months, but seemed on the road to recovery when the hæmorrhage occurred. He was well known in the mineralogical world as one of the most assiduous and able of private collectors, and his valuable collection was one of the objects of interest which foreign mineralogists visiting this country wished to consult. He has carried out his intention, announced several years ago, of bequeathing the collection to the Jermyn Street Museum. This gift will render the collection of this museum second only to that of the British Museum, and will, in fact, render it a formidable rival in the case of some of the rarer and more beautiful minerals. Mr. Ludlam was always willing to allow his mineralogical friends to consult his collection, and also frequently supplied them with specimens for examination.

THE Council of the Society of Arts have awarded medals to the following gentlemen for papers read during the session which is just over:—Major-General H. Y. D. Scott, C.B., F.R.S., for his paper on "Suggestions for Dealing with the Sewage of London;" A. J. Ellis, F.R.S., for his paper on "The History of Musical Pitch;" John Sparkes, for his paper on "Recent Advances in the Production of Lambeth Art Pottery;" Henry B. Wheatley, F.S.A., for his paper on "The History and Art of Bookbinding;" W. Holman Hunt, for his paper on "The Present System of Obtaining Materials in use by Artist Painters, as compared with that of the Old Masters;" Thomas Fletcher, for his paper on "Recent Improvements in Gas Furnaces for Domestic and Laboratory Purposes;" John C. Morton, for his paper on "The Last Forty Years of Agricultural Experience;" Prof. Heaton, F.C.S., for his paper on "Balmain's Luminous Paint;" Capt. Abney, R.E., F.R.S., for his paper on "Recent Advances in the Science of Photography."

LORD NORTON has all along protested that he is not unfavourable to the teaching of science in elementary schools, and is evidently hurt at the incredulity with which his protestation is received by those one-sided individuals who persist in judging his intentions by his actions, and not his words. He is evidently of opinion that the only difference between himself and those who would maintain the Code unaltered, is one of method. There are people so benighted as to believe that as science deals with *things*, it is hopeless to teach it apart from these things; who believe that if you want to make children know what a daisy or a buttercup is like, and to understand its structure, the shortest and most effectual way is to show them the flower and take it to pieces in some sort of systematic way before their eyes. But these people are all wrong. Why should children and teachers put themselves to the trouble of soiling their hands by pulling to pieces nasty weeds, when the thing can be much better done from books? Lord Norton, as we learn from a contemporary, has resolved to triumphantly refute these deluded people, by himself compiling a series of reading lessons in botany, warranted to teach the children of our elementary schools all that it is safe and wholesome for them to know. Evidently modern science and its methods are all wrong; books, after all, are the only instruments of education, and the sooner we make a holocaust of all modern scientific implements and methods the better. Might we suggest to Lord Norton that after he has completed his botanical enterprise he might compile a series of lessons in engineering, civil and mining, for the purpose of saving the neophytes in these departments the necessity for spending their time in sooty workshops and stifling mines? In fact there seems no end to the enterprise which Lord Norton is about to "inaugurate;" if he is able to carry it on to completion, he will probably earn for himself a right to be considered the most remarkable educationist of his time. In the meantime Her Majesty's reply to the address which the Lords were persuaded to adopt is virtually a quiet snub; while in the Commons Mr. Mundella has declared that the Government have no intention of lowering the standard of education in the country. Does not this look rather bad for the success of Lord Norton's projected compilation?

IT is a tacitly-accepted practice, and one so beneficial to student-readers as to be almost imperative, that writers of original scientific memoirs should, wherever their researches touch upon common ground with those of older workers of standing, give references (at the very least in a decent foot-note) by which the student may be able to turn at once to the *ipsissima verba* of the possible authorities. We regret to notice an increasing tendency of late to slovenliness in the way of making such references on the part of some of the younger generation of enthusiastic would-be discoverers. Even the *Proceedings* of the Royal Society itself are not exempt from this modern weed, for in a recent paper we find the following given as references:—*Phil. Mag.*, 1850, *Pogg. Annalen*, 1858, and—for an important deduction from a paper by Clausius—*Phil. Mag.*, 1851. Is it too much to request the writers of Royal Society papers to be at least a little more explicit in their allusions? We cannot suppose that such references are made vague with any sinister purpose.

DR. P. P. C. HOEK of Leiden writes:—"The zoological station of the Netherlands Zoological Society for the summer months of this year is erected in the neighbourhood of Nieuwediep Harbour. The use of the station is free to the members of the Society and to strangers introduced by one of the members. The laboratory is furnished as completely as possible with all the implements—optical and steel instruments excepted—necessary for anatomical, histological, and embryological researches; it contains also a small collection of books necessary for a preliminary investigation and determination of the animals collected, &c. Special arrangements of a very simple but practical kind serve to keep alive the collected animals. Smaller and larger

excursions are organised every year by the station, and for these it always has at its disposal pilot-boats and other small vessels of the Dutch marine. Since its opening, in the summer of 1876, the station has repeatedly received proofs of appreciation from different quarters. Thus on the Scotch coast a similar station has been erected after the drawings and notes furnished by the Dutch Society; the International Exhibition of Fish and Fisheries, this year held in Berlin, rewarded the practical side of the institution with a silver medal. Further particulars may be obtained from the Secretary of the Commission for the Zoological station."

Dr. Hermann Müller's long-promised work on Alpine Flowers is being printed, and will be published towards the end of the year.

Mr. Daniel Grant has given notice that he will to-day ask the First Commissioner of Works whether he will take into his consideration the advisability of substituting the electric light for the purpose of illuminating the House in place of the gas now used in the roof.

The annual exhibition of the Photographic Society at Pall Mall will open on Saturday, October 2, and close on November 13. Friday, September 24, is the last day on which pictures can be received.

The *Times* Geneva correspondent writes under date June 20 that a remarkable electrical phenomenon occurred at Clarens on the afternoon of Thursday last. Heavy masses of rain-cloud hid from view the mountains which separate Fribourg from Montreux, but their summits were from time to time lit up by vivid flashes of lightning, and a heavy thunderstorm seemed to be raging in the valleys of the Avants and the Alliaz. No rain was falling near the lake, and the storm still appeared far off, when a tremendous peal of thunder shook the houses of Clarens and Tavel to their foundations. At the same instant a magnificent cherry-tree near the cemetery, measuring a metre in circumference, was struck by lightning. Some people who were working in a vineyard hard by saw the electric "fluid" play about a little girl who had been gathering cherries and was already 30 paces from the tree. She was literally folded in a sheet of fire. The vine-dressers fled in terror from the spot. In the cemetery six persons, separated into three groups, none of them within 250 paces of the cherry-tree, were enveloped in a luminous cloud. They felt as if they were being struck in the face with hailstones or fine gravel, and when they touched each other sparks of electricity passed from their finger-ends. At the same time a column of fire was seen to descend in the direction of Chatelard, and it is averred that the electric fluid could be distinctly heard as it ran from point to point of the iron railing of a vault in the cemetery. The strangest part of the story is that neither the little girl, the people in the cemetery, nor the vine-dressers appear to have been hurt; the only inconvenience complained of being an unpleasant sensation in the joints, as if they had been violently twisted, a sensation which was felt with more or less acuteness for a few hours after. The explanation of this phenomenon is probably to be found in Prof. Colladon's theory of the way in which lightning descends, as described in Nature, vol. xxii. p. 65. The Professor contends that it falls in a shower, not in a perpendicular flash, and that it runs along branches of trees until it is all gathered in the trunk, which it bursts or tears open in its effort to reach the ground. In the instance in question the trunk of the cherry-tree is as completely shivered as if it had been exploded by a charge of dynamite.

The number of lions in Algeria is fast diminishing, and it is expected that the animal will soon be extirpated from the colony. As there is an increasing demand for public exhibitions at fairs and zoological gardens, an establishment has been formed at Bona, by a private individual, for lion-breeding.

The Commission for the construction of the Trans-Saharan Railway has determined that this great work shall be preceded by the establishment of a telegraph line connecting Algiers with St. Louis in Sengal *viâ* Timbuctoo.

We hear that Mr. J. R. Gregory, the well-known mineral dealer in London, has been awarded at the Sydney Exhibition a *first class*—equal to a gold medal—and a *third class*, for his collections of minerals and fossils, and geological collections.

We are asked to state that the business of Messrs. R. and J. Beck, the manufacturing opticians, has been removed from No. 31, Cornhill, to No. 68, Cornhill.

The success achieved by M. Paul Desmarets in his balloon photographs, to which we referred last week, has created some sensation in the scientific world of Paris. The photographs obtained by him at Rouen were exhibited and explained by M. de Fonvielle in a lecture delivered at Versailles Mairie on June 22, at a sitting of the Société des Sciences Naturelles. They have been presented by MM. Paul Desmarets and Jovis to the Minister of War; M. Janssen will present them at the Academy of Sciences, and M. W. de Fonvielle to the Geographical Society. One of the photographs will be published next Saturday in the *Monde Illustré*, having been photographed on wood and engraved. The electrical apparatus which enabled M. Paul Desmarets to obtain his *clichés*, and the obturators have a weight of 700 grammes only, including the elements required. Steps are being taken for the systematic photographing of Paris and vicinity. One plate shows a piece of land covered with houses, gardens, and roads in the vicinity of Rouen, measuring 300 yards by 300 yards, and executed on the scale of $\frac{1}{8000}$. The altitude was about 1,100 metres. The second photograph was in the direction of W.N.W., facing the horizon. All the Seine, from Rouen Railway Bridge to Guellebœuf, is seen with wonderful distinctness. The city of Rouen was concealed by a dense cloud, and is lost in darkness. The details on the banks can be magnified and examined at leisure. This remarkable ascent was made from Rouen on June 14, with *Gabriel*, a new balloon of 1,200 cubic metres belonging to M. Tovis, and built for the express purpose of crossing the Channel, weather permitting. It is owing to the uncertainty of the weather that this enterprise, of which we have spoken already, has been postponed.

We learn from a circular forwarded to us that the Epping Forest and County of Essex Naturalists' Field Club will hold their next Field Meeting on Saturday afternoon, July 3, for the purpose of thoroughly inspecting the ancient earthworks of Ambresbury Banks and Loughton. The archæological conductor for the occasion is Major-General Pitt-Rivers, F.R.S.

M. Tessie du Motay, a French chemist who had invented a continuous process for the preparation of oxygen gas and apparatus for oxyhydric lighting, has recently died at New York at the age of sixty-two.

The excursions arranged for by the Geologists' Association are to Maidstone on July 10, Leith Hill and Dorking July 24, and Bristol on August 16 and five following days.

On Tuesday evening Signor Alberto B. Bach gave a lecture at the Royal Academy of Music on the cultivation of the voice, and on his invention, the Resonator, an instrument somewhat of the nature of an artificial palate, intended to increase the power of the voice without any additional expenditure of breath.

Natural caverns of enormous size—one being 600 feet long—have been discovered within the last few days in the neighbourhood of West Harptree, near Wells, in Somerset. The investigations are still being carried on, and the discoveries have excited some interest among antiquaries and archæologists.

In a paper read at the last meeting of the Statistical Society, by Mr. R. Price Williams, C.E., "On the Increase of Population in England and Wales," the author said the total increase of the population of England and Wales during the whole of the last century was only 3,417,536, the average decennial rate of increase being nearly 5 per cent., whereas during the present century, up to 1871, there was an increase of nearly 14 millions, the average decennial rate of increase being over 14 per cent. The rate of increase in the decade 1811-21 was the maximum attained in this century, viz., 18 per cent., as from that period down to the census of 1861 the rate of increase of the population had continuously diminished. He observed that a great increase of the population took place at the time when steam-power began to be used for manufacturing purposes, and while the towns increased, the rural districts were found to diminish. Mr. Williams estimates that the population of England and Wales by the census of 1881, will be 25,735,900. In the case of the population of London the decrements were very slight indeed, showing that it had not reached that declining stage in the rate of its increase long since arrived at in the case of Liverpool, Manchester, and many other large towns. The population of London had increased from 958,863 in 1801 to 3,251,913 in 1871. He did not think there was sufficient data for estimating the future increase of the population of London for any lengthened period, and he regarded as unreliable the enormous estimates which had recently appeared in connection with the question of the water supply of the metropolis, where the population in the course of the next century was estimated at over 17 millions.

The Thirteenth Annual *Report* of the Peabody Institute of Baltimore testifies to the increasing usefulness of that institution, both as a library and as a centre of varied instruction. Among its means of usefulness are a series of lectures, many of which are on scientific subjects.

We have received the *Report* of the South African Museum for 1879, from which we are pleased to see that the Museum is in a fairly flourishing condition. A long list of additions during the year is appended.

The May and June numbers of the Friends' Schools' *Natural History Journal* contain much interesting matter, the local papers being specially valuable.

The additions to the Zoological Society's Gardens during the past week include an Arabian Gazelle (*Gazella arabica*) from Arabia, presented by Capt. Titus; a Common Genet (*Genetta vulgaris*), South European, presented by Mr. G. H. Thunder, R.N.; an Emu (*Dromæus novæ-hollandiæ*) from Australia, presented by Mr. A. McIlwraith, F.Z.S.; a Greater White-crested Cockatoo (*Cacatua cristata*) from Moluccas, presented by Mrs. A. L. Chetwode; three Red-beaked Weaver Birds (*Quelea sanguinirostris*) from West Africa, presented by the Marchioness of Westminster; a Crested Ground Parrakeet (*Calopsitta novæ-hollandiæ*) from Australia, presented by Miss M. S. Spooner; a Barbary Ape (*Macacus inuus*) from North Africa, an Ocellated Monitor (*Monitor ocellata*) from West Africa, deposited; three Ruddy Sheldrakes (*Tadorna rutila*), European, two Sandwich Island Geese (*Bernicla sandvicensis*) from the Sandwich Islands, two Blood-rumped Parrakeets (*Psephotus hæmatonotus*) from Australia, two Celebean Rails (*Rallus celebensis*) from Celebes, purchased; a Collared Fruit Bat (*Cynonycteris collaris*), a Japanese Deer (*Cervus sika*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

The Third Comet of 1822.—Neither Galle in his catalogue, nor Karl in his *Repertorium der Cometen-Astronomie*, refers to any observations of this comet except the imperfect ones made by Caturegli at Bologna, and two by Gambart at Marseilles, and the only orbits found in the catalogues are the two calculated by Heiligenstein. The comet was however observed at Rio de Janeiro, from June 18 to June 24, and Henderson reduced the observations, which were made by Lieut. Robertson, R.N., and calculated an approximate orbit upon them. The comet approached near to the earth, and is of some interest upon that account. Mr. Hind has combined the observations of both hemispheres, and with the following results for the elements of the orbit: Henderson's numbers, not being found in our catalogues, are annexed:—

	Hind.		Henderson.
Perihelion passage	July 15·8442 G.M.T.	...	July 15·651 G.M.T.
Long. of perihelion	219° 59′·4	...	220° 19′ 49″
,, Ascending node	97 44·3	...	98 14 47
Inclination of orbit	36 17·5	...	35 36 0
Log. perihelion distance ...	9·92797	...	9·92879

Motion—retrograde.

Henderson's paper upon this comet will be found in the *Philosophical Transactions* for 1831. On June 18 the comet was in opposition to the sun, distant from the earth 0·14. Though it was discovered by Pons at Marlia on May 30, we have no observation previous to June 8. Pons at the time was not provided with instruments competent to fix the positions. Zach writes of the comet at the time of discovery that it was without tail or nucleus, simply a nebulosity more condensed towards the centre. Pons thought that in the absence of moonlight it would have been visible without the telescope. He was then on the watch for Encke's comet, which, though not observed in Europe, was closely followed by Rümker at Paramatta, N.S.W.

The Double-star 85 Pegasi.—Mr. Burnham publishes measures of the small and close companion of this star made in the summer of 1879, which, compared with those he obtained the previous year when he detected this very faint object, establish its physical relation to the principal star, since it is shown to partake of its large proper motion, while a suspicious difference of 10° between the means of the measures in 1878 and 1879 points to its binary character. These means are as follow:—

1878·43 ...	Position 274°·0 ...	Distance 0″·67 ...	3 nights
1879·46 ...	,, 284·6 ...	,, 0·75 ...	5 nights

Mr. Burnham estimates the magnitude of the close companion about the twelfth on Struve's scale, and considers it will require an aperture of at least twelve inches to show it. He has also measured the distant companion which was used by Prof. Brünnow in his investigation of the parallax of 85 Pegasi, which he made to be 0″·054. This star was observed with 85 at Königsberg by Bessel on October 6, 1825, when it followed 61″·95 in R.A., and was 38″·6 south of the bright star. If we compare these differences with those corresponding to Mr. Burnham's measures at the epoch 1878·95, and assume the fixity of the companion, we shall find for the secular proper motion of 85 Pegasi in R.A. + 100″·1, and in Decl. − 96″·1, agreeing precisely with the values resulting from a comparison of the meridian observations. If, as Prof. Brünnow hinted, there is proper motion of the distant companion, its amount would appear to be very minute. Mr. Burnham adds that there are but two other stars on our lists similar in character to 85 Pegasi, viz., η Piscium and β Scorpii; all three were detected by him with the 18-inch Chicago refractor.

A Variable Star in Aquarius.—The star observed on six nights at Bonn, in 1863, in R.A. 22h. 28m. 16·9s. N.P.D. 98° 21′ 19″ for 1855·0, is variable from 9m. to invisibility in a 7-inch aperture. Argelander noted it four times 9·5, once 9·6, and once 10·0. It was observed at Markree as a 9m. on October 27, 1848, on August 26, 1852, it was 11m., and on November 9, 1874, it was invisible. On September 21, 1876, it was 11·12. It has at times a hazy blurred appearance, as remarked in several other variable stars. This star was long since indicated as variable, but appears to have escaped attention from most observers of this class of objects.

GEOGRAPHICAL NOTES

Dr. Francisco Pereira Passos, Director of the Brazilian State Railways, has recently caused to be prepared and published a map showing the existing and projected railways in the provinces of Rio de Janeiro, Minas, and San Paulo. This map is

apparently executed with much care, and is stated to be the most accurate of its kind yet produced in Brazil. He has also published the first part of a work on the railways of Brazil in 1879, descriptive of the lines shown on the above-mentioned map, and he has added a skeleton map showing the railways only. Dr. Passos has, we believe, been induced to issue these publications in order to make more widely known in England the progress in railway communication now going on in Brazil, a subject which is of considerable interest from an economical and geographical point of view.

THE last *Bulletin* of the Antwerp Geographical Society contains a geographical and commercial essay on the Australian colonies, which is accompanied by reproductions of some curious old maps, as well as by a sketch map which professes to distinguish the arable, pastoral, and desert regions of the continent, in regard to which, however, the writer's information hardly appears to be brought down to the latest date.

FROM the Japan papers we learn that H.M.'s surveying vessel *Sylvia* left Hiogo on April 24 for Cape Chichakoff to take a line of soundings there, which will complete her surveying work on the Japanese coast. The *Sylvia* has been employed for about twelve years in surveying the coasts of Japan and the Inland Sea, and during this period has done excellent service to navigation.

M. DE UJFALVY is to leave Paris at the end of the summer on his new journey of exploration in Central Asia.

THE *Times* correspondent writes from Copenhagen that on June 24 died there Mr. Carl Petersen, whose name is connected with some of the most renowned Arctic explorations. He was a born Dane, but had lived many years in Greenland, and had there acquired a perfect knowledge of the Esquimaux language, being at the same time a most skilled hunter and fisherman. At the age of thirty-seven he was engaged by Capt. Penny as interpreter, and accompanied his expedition in the years 1850-51. Some years later he followed Dr. Kane on his unfortunate expedition, when the vessel had to be left in the ice and the crew were nearly starved and frozen to death. He had not been home more than a couple of weeks after returning from a two years' stay in Greenland, before he went out again as interpreter with the *Fox*, Capt. Sir Leopold M'Clintock, with Mr. (now Sir) Allan Young as sailing master. Of this expedition, lasting from 1857 to 1859, and leading to the discovery of the fate of Sir John Franklin, he has written a graphic description, supplying many details wanting in the well-known book of Sir L. M'Clintock, and inscribed with the words chosen by Jane Franklin for the flag of the *Fox*, "Hold fast," happening to be quite as correct in Danish as in English. In 1861 he accompanied the Swedish naturalists Nordenskjöld and Torell on their first expedition to Spitzbergen, and when, in last April, the *Vega* passed Copenhagen, the hardy old sportsman and sailor, with his cross and Arctic medal, was one of the friendly faces greeting the discoverer of the North-East Passage. Mr. Petersen died from heart-disease at the age of sixty-seven.

PHYSICAL NOTES

ONE of our electrical contemporaries across the Channel gives a glowing description of *une grande machine électrique allemande*, which its editor says he wishes to see introduced into France, "where our official professors appear to have lost all ambition at making things big." The great gooseberry of the season is nothing to this new machine, which is, we are told, composed of twenty parallel disks of 1,300 metres in radius. This is "making things big" with a vengeance, for the diameter of the disks will be over 2½ kilometres, or about a mile and a half. Did our contemporary make a double blunder when it wrote "*treize cents mètres*"? If we remember rightly, the plates in Töpler's induction-machine, which appears to be the one referred to, are not far from 13 centimetres radius.

PROFESSORS BRACKETT AND YOUNG have made a new determination of the efficiency of Edison's dynamo-electric generator and of his carbon horse-shoe lamp, and find that one horse-power applied at the dynamometer would produce in this lamp a light equal to that of 107 standard candles. As a matter of fact the lamp was only giving a light of 10·7 candles while consuming 0·077 of a horse-power, which is not quite the same thing.

PROF. QUINCKE has lately been occupied with a very remarkable research on the alteration of volume which a dielectric experiences under the stress of an electric charge. In most cases the result of surface electrification is to produce a minute expansion, but one class of bodies—that of the fatty oils and resins—contracts under similar circumstances. Herr Quincke applies his measurements to explain the phenomena observed by Kerr of the double refraction of light exhibited by dielectric media when under electrostatic strain; and he shows that the optical effects in the two classes of media are opposite in character.

M. MOUCHET is continuing in Algeria the researches on the utilisation of solar heat which he began in the South of France. He employs, according to his recent communication to the *Comptes Rendus*, a mirror 3·8 metres in diameter to concentrate the rays of the sun upon a boiler of copper 5 millims. thick. Even on dull days the apparatus boils water under half an hour. M. Mouchet has employed his apparatus for the distillation of oils and essences, the boiling of linseed oil, and the sublimation of benzoic acid. He has even succeeded in working a small engine.

MR. G. R. CAREY of Boston has published in the *Scientific American* a suggested system for the transmission of light by electricity. A camera throws an image of the object to be exhibited upon a surface made up of small pieces of selenium, each of which forms part of a separate voltaic circuit, the circuits passing to a receiving instrument, where they reproduce the image by incandescence. To this Mr. Sawyer has appended the following criticisms:—The action of light in altering the conductivity of selenium is slow. To transmit satisfactorily an image one inch square would require 10,000 selenium points and 10,000 conducting wires, unless some principle of isochronous movement could be devised—which Mr. Sawyer regards as unattainable in practice.

M. FAYE has lately published in the *Comptes Rendus* a remarkable paper on the physical forces which have produced the present figure of the earth. After remarking on the use of the pendulum in determining the figure of the earth from series of measurements of the intensity and direction of the gravitation force at different parts of the earth's surface, he draws attention to the curious fact that while the direction and intensity of gravity are affected perceptibly by the presence of hills such as Schiehallion and Arthur's Seat, or even by masses as small as the Great Pyramid of Gizeh, gigantic mountains such as the Himalayas, and great elevated plateaux and table-lands do not affect the pendulum-indications in any sensible manner, except in certain cases where upon elevated continents there appears to be a veritable defect of attraction instead of the excess which might be expected. Indeed, the observations are sufficiently striking to seem to point to the supposition that not only under every great mountain, but even under the whole of every large continent, there were enormous cavities. More than this, the attraction at the surface of all the great oceans appear too great to agree with the distribution presumed by Clairaut's formula, which is exact enough for most purposes. Sir G. Airy's suggestion that the base of the Himalaya range reaches down into the denser liquid interior, and there displaces a certain amount of that liquid, so that the exterior attraction is thereby lessened, is one which, inherently improbable, fails to have any application in explaining why the attraction above the seas should be greater than over the continents. M. Faye propounds the following solution to the difficulty:—*Under the oceans the globe cools more rapidly and to a greater depth than beneath the surface of the continents.* At a depth of 4,000 metres the ocean will still have a temperature not remote from 0° C., while at a similar depth beneath the earth's crust the temperature would be not far from 150° C. (allowing 33 metres in depth down for an increase of 1° in the internal temperature). If the earth had but one uniform rate of cooling all over it, it would be reasonable to assume that the solidified crust would have the same thickness and the same average density all over it. It is therefore argued that below the primitive oceans the earth's crust assumed a definite solid thickness before the continents, and that in contracting, these thicker portions exercised a pressure upon the fluid nucleus tending to elevate still further the continents. This hypothesis, M. Faye thinks, will moreover explain the unequal distribution of land and sea around the two poles; the general rise and fall of continents being determined by the excess of density of the crust below the oceans, and by the lines or points of least resistance to internal pressure being at the middle of continents or at the margin of the oceans.

SOME experiments have lately been made by the Rev. Dr. Haughton and Prof. Emerson Reynolds to evaluate the coefficient of friction (*i.e.* the "drag") of air upon air and of water upon water. In these experiments a spherical ball of unpolished granite of 22 kilogrammes weight and 25 centimetres in diameter was suspended freely by a pianoforte wire and was set rotating in the air or in water; the period of the vibrations and the decrement of their amplitudes being observed by means of indices attached to the brass collar by which the ball was suspended. A discussion of the equations of motion led to a simple working equation for reduction of results. The mean coefficient of friction found for air upon air was $f = \frac{1}{6052 \cdot 7}$, though this value apparently differed slightly according to barometric and thermometric conditions. For the "drag" of water upon water the value found was $f = \frac{1}{307}$. These experiments involved friction at low velocities only, for which it could be assumed that the friction was proportional to the velocity. The authors of this research point out that these results tend to negative the theory of Dr. Carpenter that the phenomena of ocean circulation are due to the greater height of the water at the equator as compared with that at the poles.

FROM a series of experiments with tones produced by a limited number of impulses, Herr Kohlrausch finds (*Wied. Ann.*, No. 5) that a tone of only two vibrations of a certain frequency can be distinguished as differing in pitch from a continuous tone, when it forms with it an interval of $\frac{8}{8}\frac{1}{0}$. Also, in agreement with the researches of Herr Exner and Herr Auerbach, the possible sharpness in definition of the pitch of a tone by an ear of average fineness does not perceptibly increase after sixteen vibrations have occurred. The general results are regarded as confirming Helmholtz's theory of the co-vibration of tone-perceiving organs in the ear. The experiments were made with a pendulum fitted with a piece of toothed wheel, of radius equal to the length of the pendulum, the teeth impinging on a piece of cardboard. The continuous tone was obtained from a monchord.

THE torsion of wires of steel, iron, and copper has been recently made a subject of experiment by Herr Warburg (*Wied. Ann.*, No 5). Among other results, the statically-determined moments of torsion are found to be all smaller than those dynamically determined; and the differences rise from 1 per 1,000 for steel to 6 for iron and 28 for copper. The elastic pressures seem to increase somewhat more slowly than the deformations, the divergence being greater for copper than for iron, and for iron than for steel. No dependence of the coefficients of torsion on the tension was discoverable (within the limits of experiment). As to the properties of wires that have undergone permanent torsion, it appeared that it was only in the case of soft copper wires that, within wide limits of permanent torsion, these extend almost uniformly over the whole wire. Confining himself to copper wire, then, his experiments lead him to believe that by permanent torsion the wire becomes anisotropic, behaving, at any part, like a crystal of the rhombic system, whose axes have certain directions.

ATTENTION has been called by Herr Holtz (*Wied. Ann.*, No. 5) to an optical illusion in looking at geometrical figures, whereby they appear shorter from right to left than they really are; a square, *e.g.*, appearing more or less as a rectangle, and a circle as an ellipse. One direct consequence is that when we draw such figures according to eye-measurement, we make them too long horizontally. The reason of the illusion Herr Holtz considers to be that, in common life, we much more frequently encounter bodies than geometrical figures, and so are disposed to accept the outlines of such figures for the outlines of actual bodies. Now we see more of a body in a horizontal direction than in a vertical, because we see with two eyes, and these are in a horizontal line. The outline of a ball appears to us really as an ellipse, because, from right to left, we see more than half of the ball. When we see a true circle this seems horizontally shortened, because we take it for the outline of a ball, and if we draw a circle we unconsciously give the outline of a ball.

SOME researches by Herr Röntgen in the same line as those by Dr. Kerr, revealing a new relation between light and electricity, are described in the *Annalen der Physik*, No. 5; the methods were somewhat varied. Special attention was given to the direction of vibration of the light in the liquid, and the author's results seem in the main to confirm Dr. Kerr's views. Dr. Kerr got an effect with nitro-benzol only when a spark-interval was introduced in the connection of the one electrode with the conductor of the machine, giving a sudden discharge through the liquid. This Herr Röntgen considers due to the comparatively good conductivity of nitro-benzol; the spark discharge effects a brief but large difference of potential (not obtained in the other case), producing sudden luminosity in the field of vision. But Herr Röntgen obtained the same effect with all the badly-conducting substances he examined; it was only of longer duration. A welcome method is thus afforded for examining comparatively good conducting liquids as to electro-optic properties, and Herr Röntgen thus demonstrated, for glycerin, sulphuric ether, and distilled water, an influence of electricity on the transmitted light. The author offers (doubtfully) a different hypothesis of the phenomena to that of a direct action of electricity on the light vibration.

IN a recent paper in the *Annalen der Physik*, No. 5, Prof. Clausius criticises recently-published views of Maxwell, Frowein, and Korteweg on the mean length of path of gas molecules.

PHYSICAL SCIENCE IN RUSSIA

WE have before us the minutes of the meetings of the Physical Section during the last congress of Russian naturalists, just published in the last number of the *Journal* of the Russian Physical and Chemical Society (vol. xii., fasc. 4), and we find in them reports of several very interesting papers which were read and discussed during the congress.

The most numerous communications were on electricity. Thus, M. Feploff exhibited the new electrophoric machines of his invention. A glass of sulphuric acid is sufficient for maintaining the machine ready, even during moist weather; it gives very powerful sparks, white and coloured, and succeeds well in decomposing water.—Prof. Khvolson made a communication on corrections to the differential equations of the motion of a magnet which oscillates under the influence of a metallic tranquilliser, and discussed the method of computation of corrections to differential equations of motion in general.—M. Tchikoleff gives the equations for determining the losses which an electrical current experiences when passing through telegraphic wires.—Prof. Stoletoff has terminated his experiments for determining the ratio between electro-magnetic and electro-static units (v of Maxwell). He undertook his experiments in 1876, but had not terminated them at that time; recently MM. Ayrton and Perry have determined the value of v by a method analogous to his own, which differs from theirs in measuring a current produced by a series of successive discharges, by means of a rotating commutator, the velocity of rotation of which is measured by means of a chronograph. The preliminary experiments have given a velocity very near to that found by other researches, *i.e.*, about 300,000 kilometres per second, and Prof. Stoletoff expects to obtain more exact figures.—M. Borgmann continues his experiments for determining the heating of iron by intermittent magnetisation. The experiments are very difficult, because of the inductive currents, but they have already shown that a change in the magnetic state produces an increase of temperature.—Prof. Lemström (Helsingfors) made a communication on his most important work on the causes of terrestrial magnetism. He has demonstrated that an annular isolator, when put in rapid rotation around an iron cylinder, acts upon this last as a galvanic current and magnetises it. Likewise an iron cylinder when rapidly rotating in an insulating medium must be magnetised, and thus the earth when rotating in an atmosphere of ether must also be magnetised. The various peculiarities observed as to terrestrial magnetism might be easily explained by the motion of the earth around the sun, and by the terrestrial galvanic currents.—M. Tchikoleff explained his improvements in the Foucault electric lamp, which allow several lamps to be placed in one circuit.—Prof. Petrushevsky made an interesting communication on his measurements of the intensity of the magnetic field between the extremities of electro-magnets of various shapes, which measurements were made for determining the best shape to give to electro-magnets. That of Ruhmkorff proved to be twice as strong as that of Gramme. The best shape is that of two iron cylinders united together by means of arcs made of broad iron plates. The free ends must be provided with two spherical pole-pieces, each of which has a conical processes, the ends of these two processes being directed one to another.

In meteorology we notice several valuable papers, the most important of them being that by M. Woeikoff on rainfall in

various parts of the earth within different seasons.—Prof. Krayevitch, who has undertaken a series of investigations on the very small changes of pressure of the air in connection with changes of weather, exhibited his new graphic very sensitive barometer, the column of which consists of water and mercury, and which amplifies 140 times the oscillations of a common mercury barometer.—Prof. Egoroff has begun a series of researches into the atmospherical lines of the solar spectrum. As known, several of them are due to the presence of water-dust in the atmosphere, and Ångström supposed that several other lines (A, B, and *a*) depend upon the presence of carbonic acid and nitrogen. The experiments of M. Egoroff show that neither of these two gases modifies the solar spectrum, even when the rays go through a sheet five metres thick of gas.

In other branches of physics we must but notice the most important work, by Prof. Tchebysheff, on centrifugal regulators; the researches by M. Sloughinoff on the calorific capacity of gases; by Prof. Petrushevsky on the velocity of evaporation of liquids with reference to the coefficients of cohesion of these liquids and to the molecular pressure; on the true atomical heat capacity, by M. Stelson, who arrives at the conclusion that the theory of a constant atomic heat-capacity is not true for many gases; and by M. Sloughinoff, on the powder-state of bodies, and on the changes of the internal energy of solids and fluids under the influence of exterior forces.

We notice also the communication by M. Lebedzinsky on an improved microscope with liquid lenses, which gives enlargements from 50 to 200 times, and is very cheap; and by M. Argamakoff on lighting and heating by means of pulverised hydrocarbons.

SEISMOLOGY IN JAPAN

The Earthquake of February 22, 1880.—The earthquake which occurred shortly after midnight on the morning of February 22 was the most severe since the opening of this country to foreigners. I have been so much in the habit of noting my watch during the frequent earthquake manifestations by day and night, that I am sure I must have been instantly awakened. My house was swaying to and fro, windows were rattling, timbers creaking, mortar falling, and pictures swinging violently. Although, as usual on such occasions, I was studying my watch by a night light, I meditated escape. After forty seconds the motion apparently subsided. There had been two distinct periods of maximum intensity. Taking my lamp, I tried to reach the door, but the motion was still so great that I had to stop, supporting myself against the wall. When I went down stairs to look at two long pendulums of 20 and 30 feet length respectively, I found them swinging in arcs of about 2 feet, having broken all the apparatus on the table over which they hung. Hitherto the pointers placed on heavy weights suspended by long wires have been regarded by me as motionless points during an earthquake, and I have been able to use them accurately on this assumption even for a shock which Palmieri's instrument indicates as 21°, a shock which knocked down several chimneys. It would seem that in the last earthquake the house, instead of, so to speak, "eating up" the vibrations, was forced into vibration itself. The period of this vibration was roughly noted by my neighbour, Mr. Thomas Gray, as nearly one second. At the lower end of one of these pendulums I have small pointers which scratch two smoked glass plates. These plates are caused to move away during an earthquake, so that relative vibrations are shown in two wavy lines. The direction of the first mark upon the plate tells the direction of the shock, and also the distance moved by the earth relatively to the steady pointer. The amplitude of the waves tells approximately what the movement has been during succeeding vibrations. From the number of waves upon a given length of glass we get the rate of vibration, and hence, knowing the velocity of transit, the true wave-length of the earthquake may be determined. As an example I may mention that an earthquake (December 3, 1879) registered by Palmieri's instrument as 18°, was recorded on 7 inches of one of my glass plates in a curve of seven very small waves, the amplitude of each of which was about 1 mm. Each wave was formed in half-a-second. The important deductions which may be drawn from even only one observation of this kind are obvious. The other pendulum I have used only for finding the greatest horizontal movement of an earth particle and its direction. Two pointers push against the motionless pendulum-bob when an earthquake occurs, and so they are moved in the stand which carries them, deflecting two suspended galvanometer mirrors, and readings of the amount of deviation of beams of reflected light are taken. I give some examples of the movement of the head of a pile which was driven deeply into the soft soil upon which Yedo is built:—

1. March 4, 1879, 4.43 p.m.—On the smoked glass the mark made was 3 mm. long; N. 10° E. to S. 10° W. Palmieri's instrument gives this shock of intensity 10° from S.S.W. to N.N.E.

2. February 1, 1880.—Small shock. Mark 1·25 mm. from N. 35° W. to S. 35° E. Palmieri's instrument gives intensity 2°·5 S.S.E. to N.N.W. As measured by the mirrors, this shock was 0·5 mm., and there is reason to believe that the mirrors were more correct. The amplitude of swing, as indicated on the moving plates, was from 3 mm. to 4 mm. At the point, however, there seems to have been a motion of about 10 mm.

As my indicating apparatus was broken, I give the following record from two of Palmieri's instruments in the Government Observatory:—

From S.S.E.	or	N.N.W.	the intensity was	78°
,, S.S.W.	,,	N.N.E.	,, ,,	52
,, W.S.W.	,,	E.N.E.	,, ,,	28
,, W.N.W.	,,	E.S.E.	,, ,,	28

These measurements had to be computed, as the graduations of the instruments are only to 26°. The shaking seems to have had three periods. The first began at 12h. 49m. 22s., and lasted 14 seconds; the second began at 12h. 50m. 19s., and lasted 1m. 26s.; the third began at 12h. 52m. 15s., and lasted 6 seconds.

On visiting Yokohama I found that the chief destruction had been amongst the houses belonging to Europeans. This is partly due to the Japanese houses being nearly as flexible as baskets, but it is also on account of the European houses being mostly buils on hills. Thus the houses built on the *bluff*, hills intersected by sharp steep valleys, and also many houses built along the *creek* have suffered; the greater part of Yokohama is built on a plain of shingle, and the houses here escaped with small damage.

The edge of a declivity is like the last of Tyndall's row of boys, unsupported on one side, and therefore gets shot forwards.

Tokei, Yokohama, Japan JOHN MILNE

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—In the first half of the winter course of lectures given in connection with the Cambridge Local Lectures the attendance of about 1,200 persons, on subjects of physical science, out of a total of 3,570, may be noted. In the second half of the session scarcely 400 were attending lectures on physical science subjects, but this was coincident with a general falling off after Christmas, to which bad weather, depression of trade, and political excitement may have contributed.

Another academic year has completely passed, and in the multitude of counsellors no relief has yet been given to those who desire freedom of choice of language studies and some chance for modern languages. The University still says: "If you have not the smattering of Greek we require, we will give you no degree unless you bring up Arabic or Sanskrit as an Oriental student."

A LIVERPOOL paper intimates that the movement for establishing a University College in that city is likely soon to be crowned with success. In the scheme which was approved at a town's meeting held some months ago it was proposed that seven professorships and two lectureships should be founded, and it was estimated that, independent of the cost of erecting college buildings, the amount required for the foundation of the college is an annual income of 3,000*l*., or a capital sum of 75,000*l*. The committee accordingly appealed for subscriptions, and the appeal has been responded to in such a hearty manner that there is every probability of the entire sum required being raised before long. Already 60,000*l*. has been subscribed for the establishment of the college, the subscriptions including several of 10,000*l*. each. Lord Derby has subscribed 10,000*l*. towards the founding of one professorship; a like sum has been given by Messrs. W., S. G., and P. H. Rathbone. Mrs. Grant of Rock Ferry has endowed another professorship with 10,000*l*.; Col. A. H. Brown and the Messrs. Crossfield have between them contributed 10,000*l*. for the founding of another chair; and it is believed a number of Scotchmen resident in the city will provide

a similar amount for a similar purpose. Several other large subscriptions have been promised to the treasurer, Mr. Robert Gladstone, bringing the total up to the amount above stated.

SCIENTIFIC SERIALS

Bulletins de la Société d'Anthropologie de Paris, tome 2, fasc. 4, 1879.—This closing number of the last year's Bulletins contains an interesting paper by M. Jacques Bertillon on the mean averages of life in the various grades of society among civilised races. His paper refers specially to France, although it supplies some comparative tables deduced from the mortality tables of other countries, while it principally aims at directing attention to the preventibility of numerous causes of early death.—M. G. Lagneau, in presenting to the Society the mortality tables for Belgium, drawn up by Dr. Janssens for 1878, referred to the predominance of phthisis in male subjects in France since 1865–66, females having before that period supplied the larger number of deaths from pulmonary tuberculosis.—M. Lunier records the results of the official inquiry which he had been authorised to make in reference to the distribution of epilepsy in the various departments of France, and with regard to station, age, sex, &c.—M. le Docteur G. Le Bon gives an interesting report of his examination of the curious collection of skulls of celebrated men, now in the possession of the Paris Museum of Natural History, which is believed to include those of Boileau, Descartes, and Gall. The mean cranial capacity for the forty-two skulls, when compared with that of forty-two skulls of modern educated Parisians, was in excess of the difference between the latter and an equal number of negroes.—The present number of the *Bulletins* contributes little of importance to the literature of local French palæontology, the most interesting of such contributions being a paper by M. Mortillet, who reports the discovery, by M. Perron, of a funereal car with traces of human bones and textile fabrics in the tumulus, or barrow, known as la Motte at Apremont, in Haute-Saône.—M. Verneau describes the Grotto de Voutré, in La Mayenne, in which a skeleton, believed to belong to the Bronze age, has been found, while a similar discovery has been made at Quevilly, near Rouen, as also at Cierges, where fragments of a dolichocephalic cranium of the neolithic type have been recovered. M. Millescamps has, moreover, drawn attention to the recent discovery by the Abbé Hamard, at Hermes (Oise) of cut flints in graves of the Merovingian age. The previous discovery between 1873 and 1875 of upwards of 20,000 flints in the Merovingian cemetery of Caranda has raised the question, which still awaits solution, whether these flints were deposited with the dead merely as objects with which the living had been most familiar, or whether their presence had any supposed protective action.—M. Zaborowski has laid before the Society the result of his examination of five Hakka skulls, and communicated the information he had received from M. de Lagrenée, French Consul at Canton, in regard to the history and pure Chinese origin of the Hakkas, who have in all ages formed the active combative element in the Chinese system, and have in recent years constituted the kernel of the Taiping rebellion.—The Abbé Durand describes a blonde African race, noticed near Laouga in 1562, and still traceable in Mozambique.—The original site of the Aryan race has again been brought under discussion by M. Henri Martin, who now inclines to the opinion, supported by M. de Ujfalvy, that a brown brachycephalic Aryan branch took precedence in Asia of the blonde dolichocephalic Aryans.—The most important paper in the present volume is M. Paul Broca's "Étude des Variations craniométriques, et de leur Influence sur les moyennes." To this is appended a valuable series of the means, variations, &c., of the cranial measurement of heads belonging to all countries and various periods.—M. Ujfalvy explained his views in regard to the opinion put forth by the Swedish anthropologist, Prof. G. Retzius, that Finland is occupied by two distinct races, the true Fin, or Tawaste, and the Carelian, or Finlander.—M. Emile Soldi, in presenting to the Society his recent work on the proportions of Greek and Egyptian statues, took occasion to refute the opinion advocated by Dr. Le Bon and M. Broca, that the Greeks followed Egyptian canons of taste in art, and that they took their models from foreigners.—M. Bataillard read a paper on the ancient workers in metals in Greece, and endeavours to trace in the tinsmiths of Dodona the direct ancestors of the modern Tsiganes, or gipsies.

Papers and Proceedings of the Royal Society of Tasmania for 1878.—R. M. Johnston, on the freshwater shells of Tasmania; gives a list and describes several new species.—Rev. J. E. Tenison-Woods, on some new Tasmanian marine shells; describes a new genus, Iosepha, for a Cominella with a plait, and several new species.—R. M. Johnston, on certain tertiary and post-tertiary deposits on islands in Bass's Strait.—F. M. Bailey, remarks on the distribution and growth of Queensland plants.—Rev. J. E. Tenison-Woods, on some Tasmanian freshwater univalves.—F. Abbott, on *Carduus arvensis*.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 10.—"On *Bacterium fœtidum*: an Organism associated with Profuse Sweating from the Soles of the Feet." By George Thin, M.D. Communicated by Prof. Huxley, Sec.R.S.

The feet of certain individuals are characterised by a peculiar powerful and fœtid odour, which is really connected with the moisture that soaks the soles of the stockings and the inside of the boots. The moisture, which comes from the skin of the soles, especially from that of the heels, has no offensive smell whilst it is exuding, but it rapidly acquires the characteristic odour when taken up by the stocking.

The fluid is an admixture of sweat with serous exudation from the blood, occurring in persons whose feet sweat profusely, and who, from much standing or walking, acquire an erythematous or eczematous condition of the skin of the soles, the local eczema or erythema being favoured by the softening and macerating effect of the sweat on the epidermis.

When a small portion of the sole of the wet stocking was teased out in water, the drop of water was found to be swarming with micrococci.

A second generation of the organism, which the author calls *Bacterium fœtidum*, was obtained by placing a small piece of the wet stocking in a test-glass, charged with pure vitreous humour. This and succeeding generations were cultivated at a temperature which varied between 94° and 98° F. The successive generations were obtained by inoculating pure vitreous humour, with requisite precautions.

In twenty-four hours the surface of the vitreous humour was always found covered with a delicate scum, which in forty-eight hours was compact and tolerably resistant.

In the scum of one day's growth and in the fluid below it organisms were found as cocci, single and in pairs, in transition stages towards rod formation, as single and jointed rods, and as elongated single rods. Many of the rods were actively motile.

The compact scum of two days' growth was sufficiently resistant to be removed in an unbroken sheet. When disturbed by the needle it fell to the bottom of the glass. It was found to contain all the forms found in the twenty-four hours' growth, and in addition long unbroken rods in transition stages towards the formation of chains of spores.

Spores were also found lying beside the empty and partially empty sheaths from which they had been discharged. Groups of single spores and pairs, identical in size and appearance with those which had come to maturity in the sheaths, were found mixed up with rods in all phases of development.

The first stage in the development of the organism is the formation of a pair from one coccus.

The next stage is that in which the whole body is wedge-shaped, the round brightly refractive coccus being found in the thick end of the wedge. Another phase, which is probably the successor of the preceding one, is the appearance of a canoe-shaped figure with the bright coccus in the centre.

Other appearances connected with the early stage of development, and probably following the wedge and canoe-shaped figures, show the organism developed into a staff-shaped body, containing two elements of very different refractive power. The coccus element is still distinct and is brightly refractive, the other element is very slightly refractive and is seen as a dull shade, with however perfectly distinct outlines.

The coccus may be at one end of the rod, two cocci may be in the centre close together with a prolongation of protoplasm on either side, or a central rod of protoplasm may have a coccus at either end.

In the next stage we have the formation of the rods characteristic of bacteria. The distinction between the coccus and the protoplasm becomes lost, although transitions are found in which faint differences of refraction still betray the two elements. The formation of rods of ordinary size, of long rods with

unbroken protoplasm, of rods with segmented protoplasm, and of rods filled with spores or cocci progresses identically with the similar formation in the *Bacillus anthracis*.

The bacterium grows in turnip infusion less actively than in vitreous humour. The observations were not sufficiently extended to determine whether the bacterium forms spores when cultivated in turnip infusion, but they sufficed to show that if such a formation takes place, it occurs much less actively than when the cultivation is in vitreous humour.

The fœtid odour of the stocking was reproduced in the cultivation glasses, although the strength of the odour diminished in successive generations.

Dr. Thin stated at the meeting that an antiseptic treatment by which the bacteria were killed in the stockings and inner surface of the soles of the boots completely destroyed the fœtor.

"Memoir on Abel's Theorem," by R. C. Rowe, Fellow of Trinity College, Cambridge. Communicated by A. Cayley, LL.D., F.R.S., Sadlerian Professor of Pure Mathematics in the University of Cambridge.

"On certain Effects of Stress on Soft Iron Wires," by J. A. Ewing, B.Sc., F.R.S.E., Professor of Mechanical Engineering in the University of Tokio, Japan. Communicated by Fleeming Jenkin, F.R.S., Professor of Civil Engineering in the University of Edinburgh.

Physical Society, June 12.—Mr. Huggins, F.R.S., in the chair.—New Members: Mr. H. B. Iuff, Mr. Adam Hilger, Mr. C. V. Boys.—Dr. Shettle, of Reading, read a paper on the influence of solar radiation on the earth's rotation. The fact established by Dr. Shettle, that the magnetic energy of a bar magnet acts along spiral lines has led him to surmise that the energy emanating from the sun and impinging on the earth on the zone of the ecliptic, traverses the earth in a spiral path and finally emerges at the magnetic poles. The spiral of energy is "right-handed" at one pole and "left-handed" at the other, like the magnetic force in a magnet and the electric discharge in Crookes' vacuum tubes. Like precession and nutation, these spiral paths are constantly changing and producing magnetic variations. He therefore infers that the magnetic poles will complete a cycle corresponding to the period of precession. Dr. Shettle thinks that bodies exhibit magnetic properties in proportion as they change the direction of the energy traversing them, and throw it into the spiral form. Terrestrial magnetism would be due to the solar radiance on this hypothesis. Gravity also would be produced; so likewise would the earth's rotation (by a kind of "magnetic whirl"), electricity, tornadoes, cyclones, water-spouts, and whirlwinds. Moreover this "spiral energy" would seem to operate throughout the whole universe.—Prof. Wiedemann, of Leipsic, made a communication on the phenomenon of interference in rays of long path, and showed how the phase of vibration of the atom or molecule emitting the rays influenced the phenomenon. Molecular collisions could operate in preventing interference. From a study of this question he was able to deduce a method of determining the pressure on the surface of the sun and stars. He mentioned that he had found that the temperature of a glowing gas in Geissler's tubes may be under 100° C., and therefore the light of the aurora or of comets might be accompanied by a low temperature. He had determined that the quantity of heat produced in a gas by the electric discharge was always the same, with the same amount of electricity, whether discharged at once or not, and that it increases nearly in proportion to the pressure of the gas. He had also determined that the heat which must be developed by a discharge in hydrogen in order to change the band spectrum of H into the line spectrum is about 100,000 calories for 1 gramme of hydrogen, and hence this might represent the amount of heat necessary to transform the hydrogen molecule into its atoms. Dr. Schuster suggested that Prof. Wiedemann should make a similar experiment with another gas, say nitrogen, as there was a disagreement about the spectra, and Prof. Wiedemann stated that he so intended.—Mr. Ridout exhibited a device for amplifying small motions. A small barrel is slung by two threads between the prongs of a metal fork in such a manner that if the fork is bodily carried to and fro the barrel will rotate round its axis. This is simply effected by making each thread, in its passage from one prong to the other, take a few turns round the barrel. To the barrel an index is attached, and the fork is then fixed on the body whose minute motion is to be indicated. The translation of the body shifts the fork and rotates the barrel, which in turn deflects the index round the face of a dial, and the magnifying power is expressed by the ratio of the diameter of the barrel to the length of the index. With this apparatus Mr. Ridout exhibited the lengthening of an iron core when magnetised by the passage of the current of two Grove's cells through an insulated wire coiled round it. By riveting a slip of brass to the iron, the unequal expansion of brass and iron under heat was also shown, the heat being generated by keeping the current flowing in the coil.—Mr. D. Winstanley exhibited his new radiograph for recording graphically the intensity of solar radiation throughout the day. It consists of a differential thermometer with one black bulb and a circular stem. The lower part of the stem is filled with mercury, the upper branches with sulphuric acid and water. The tube is mounted on a brass wheel, so that when the black bulb is exposed to the sun's rays the differential motion of the mercury causes the wheel to turn. The wheel carries a light index or marker, which is free to traverse a vertical cylinder covered with paper coated with lampblack, and leaves a white track where its point has scratched off the soot. The radiogram thus produced can be fixed and preserved. Dr. Guthrie pointed out the curious "thermal twilight" these radiograms had betrayed to Mr. Winstanley. They show that before sunrise the temperature increases, owing to solar radiation. Moreover, half an hour after sunset the index falls and remains till within a few minutes of midnight, when it mysteriously rises and sinks again, although the sun is then directly over the opposite hemisphere.—Mr. Baillie then gave the results of a study he had made into the theory of the phoneidoscope. He finds that waves simultaneously start from each side of the soap-film when the note is sounded, and meeting in the middle generate ventral points and notes. The equations of several cases were given by him, and he suggested that photography should be employed to fix the appearance of the figures, in order that they might be investigated theoretically.

Linnean Society, June 17.—Prof. Allman, F.R.S., president, in the chair.—Dr. R. C. A. Prior read a letter from a correspondent concerning the rare case of a mistletoe parasite on a mistletoe.—Lord Lilford exhibited and remarks were made on a series of skins, skulls, and horns of the Wild Sheep of Cyprus (*Ovis ophion*, Blyth).—Mr. E. M. Holmes pointed out the peculiarities of the Antheridia in an excellent example of *Polysiphonia fastigiata*, gathered at Ventnor.—Mr. F. Crisp exhibited slides prepared at the Zoological Station of Naples, illustrating the early stages of the life of invertebrates, and he also showed living specimens of the new Medusa, *Limnocodium victoria*.—Mr. C. Stewart showed microscopic sections of the growing point of chara and of the common ash.—A paper was read by Mr. F. M. Campbell on certain glands in the maxillæ of spiders. These glands, to which he attributes a secretory function (probably salivary), he finds in *Tegeneria domestica* have apertures on the inner side of the upper face of each maxilla, thence inclining towards the mouth. They are ring-like in figure, with an inclosed disk. There are integumental folds at their outlets. The glands and apertures increase in number with age, and the ducts tend to become chitinous. Glands varying somewhat in structure, but evidently similar in kind, exist in species of Liniyphiidæ, Theridiidæ, and the Epeiridæ.—Mr. S. O. Ridley made a communication on two cases of incorporation by sponges of spicules foreign to them. In a species of the genus *Ciocalypta*, Bwk., the dermis contained spicules which belonged to a species of *Esperia*, and which latter sponge had been obtained in the same haul of the dredge. In another example of *Alebion* spicules also derived from *Esperia* were likewise obtained. Thus an element of error might arise from one sponge containing skeletal structures accidentally derived from a neighbouring sponge of a different genus and habit.—Prof. Allman then called attention to the remarkable Medusa recently observed by Mr. W. Sowerby in the freshwater tank at the Botanic Gardens, Regent's Park (a notice of this appeared in our last week's issue, p. 178).—A short note from Prof. E. Ray Lankester concerning the same Medusa was also read.—Mr. F. M. Campbell read a second paper on the stridulating organs of *Steatoda guttata* and *Linyphia tenebricola*. A stridulating organ has already been described by Profs. Westring and Mason Wood in certain other of the spiders; the present observations demonstrate its existence in both sexes, and the essentials of the structure are given in detail.—Dr. G. E. Dobson, in notes on *Aplysia dactylomela*, a specimen obtained at Bermuda, but not distinguishable from the species inhabiting the Cape Verde Islands, showed that there is inequality of size in the right and left moiety in the dental rows of the lingual ribbon, and he described other structures appertaining to the mandibular plates.—Mr. G. Busk communicated some researches of

his on the Polyzoa collected in the late North Polar Expedition. Several interesting and new forms are given, while the author expressed himself in certain cases as differing in his determinations from Prof. Smitt of Stockholm.—A paper on the natural classification of the Gasteropoda (part 1), by Dr. J. D. Macdonald, was read. He refers to a communication of his published by the Society twenty years ago, wherein sexual characters, lingual dentition, and auditory concretions formed the basis of classification. With modifications this is now elaborated, and in certain groups additional value given to the lingual and labial dentition.—The sixth contribution to the mollusca of the *Challenger* Expedition, by the Rev. R. Boog Watson, was taken as read. The author treats of the Turritellidæ, and describes nine new species.—A paper by Sir J. Lubbock was read, namely, Observations on Ants, Bees, and Wasps, with a Description of a new species of Honey-Ant, an abstract of which appeared last week (p. 184).—The following gentlemen were elected Fellows of the Society:—The Rev. H. G. Bonavia Hunt, Trinity College, London; H. N. Moseley, F.R.S., University of London; the Rev. A. Merle Norman, Durham; and E. A. Webb, Turnham Green.—The President with a few parting words then closed the session.

Chemical Society, June 17.—Prof. H. E. Roscoe, president, in the chair.—The following papers were read:—On pentathionic acid, by T. Takamatsu and Watson Smith. The authors have examined the evidence for and against the existence of this substance; they conclude that it does exist, and give a new method of preparing it, by the action of a very strong solution of iodine in hydriodic acid upon lead theiosulphate.—Preliminary note on some orcinol derivatives, by J. Stenhouse and C. E. Groves. The authors have confirmed their previous conclusion that halogen derivatives of orcinol exist, containing 5 atoms of bromine, &c., both the hydrogen atoms in the hydroxyl groups being displaced.—On the determination of carbon in soils, by R. Warington and W. A. Peake. Oxidation with potassium permanganate gives 92 per cent. of the total carbon, but digestion with chromic acid, &c., only 79 per cent. The best method is combustion with oxide of copper in a stream of oxygen.—Note on camphydrene, by H. E. Armstrong. In this note the author sharply criticises a recent paper by Dr. Letts in the Berlin *Berichte*, and, as a result of some experiments, completely confirms the statement of Montgolfier that the substance formed by the action of sodium on the solid hydrochloride from turpentine oil is a mixture, and not a hydrocarbon having the formula $C_{10}H_{17}$, as asserted by Dr. Letts.—On the action of nitric acid upon diparatolylguanidin, by A. G. Perkin. Dinitrodiparatolylguanidin, melting at 205°, was obtained in red crystals, also, by a slight modification, dinitrodiparatolylurea, melting at 233°.—On some higher oxides of manganese and their hydrates, by V. H. Veley. The oxide was precipitated by chlorine from a pure solution of the acetate, and was then heated in a current of air, oxygen; hydrates, Mn_6O_{11}, $2H_2O : 2(Mn_6O_{11})3H_2O$, and $Mn_{12}O_{23}H_2O$ were obtained; but in no case was the dioxide formed.—On a new method of preparing dinitroethylic acid, by E. Frankland and C. C. Graham. This consists in passing nitric oxide into a mixture of zinc ethyl and sodium ethyl, to which a suitable solvent such as benzine has been added.—On the action of organo-zinc compounds upon nitriles and their analogues, by E. Frankland and H. K. Tompkins. The action of zinc ethyl upon phenylacetanitrile is studied.—On the action of benzoyl chloride on morphine, by C. R. A. Wright and C. H. Rennie. The end result is always dibenzoyl morphine.—An examination of terpenes for cymene by means of the ultra-violet spectrum, by W. N. Hartley. The author has examined specimens of orange oil, French turpentine, and Russian turpentine, by photographing their absorption spectra; the first two oils were free from cymene, the last contains certainly less than 4 per cent.—Notes on the purple of the ancients, by E. Schunck. The author has examined a sample of the dye still used on the Pacific coasts of Nicaragua, and finds that it contains a colouring matter soluble in boiling anilin, having all the properties of punicin obtained by him from the *Purpura lapillus* of the British coasts.—The Society then adjourned over the summer recess.

Anthropological Institute, June 8.—Major-General A. Pitt-Rivers, F.R.S., vice-president, in the chair.—Mr. F. G. Hilton Price, F.G.S., read a paper on camps on the Malvern Hills. Last September, having obtained permission from Lord Somers to excavate in any part of the camps on these Hills, he set his labourers to work, first on Hollybush Hill, on the south side of the Malvern range, and afterwards on Midsummer Hill, both of which were encircled by a deep ditch and a rampart, while in the glen between the two hills on the south side was the site of a town about 1,100 feet in length. In the interior of the ancient camp on Hollybush Hill were many hut hollows, some of which he opened, but without making any discovery. On the east face of Midsummer Hill were several lines of such hollows, which, like the rest, had been habitations, and no fewer than 214 had been counted. Along the ravines between the two hills were four tanks, having the ancient dams for holding back the water still in existence. The explorations of these camps were not very fruitful. More productive were the excavations on the Herefordshire Beacon Camp, one of the largest and strongest earthworks in the district. It had usually been looked upon as of British origin, and Mr. Price saw no special reason for doubting it. In one hut hollow much coarse black pottery was met with, and there were besides many bones of the ox, pig, horse, sheep, dog, some kind of gallinaceous fowl, and of the deer. A description was given of the huge block of syenite known as the "Divination stone." It was mentioned that in 1650 a jewelled gold crown or bracelet was found in a ditch at the base of the Herefordshire Beacon. Camden had written of it, and in a MS. said to belong to Jesus College, Oxford, it was stated to have been sold to a Gloucester goldsmith for 37*l*., who sold it to a jeweller in Lombard Street for 250*l*., who sold the stones alone for 1,500*l*. There were many traditions as to coins found there, but their dates were uncertain. Mr. Price thought this large camp, as well as those on Hollybush and Midsummer Hills, were of late Cymric or Celtic origin, that the latter camp was of earlier date than that on the Herefordshire Beacon, and that in all likelihood they were occupied by the Romano-British, as many remains of those tribes existed in the district, and the pottery seemed to date from that period.—A paper was read on religious beliefs and practices in Melanesia by the Rev. R. H. Codrington. The subject is a very difficult one, inasmuch as, the islands and dialects being so numerous, no one person's knowledge can well range over the whole. The author's information was chiefly derived from the Banks' Islands and the Solomon group, whence the most advanced scholars have come to the Melanesian Mission Station on Norfolk Island. Nothing is known to show that the Banks' Islands have been influenced by Polynesian immigration or neighbourhood; though there are still men alive who can remember a visit of double canoes from Tonga. The Banks' Islanders alone among Melanesians knew no cannibalism and wore no dress. The Banks' Islanders distinctly recognise two orders of intelligent beings different from living men; they believed in the continued existence of men after death in a condition in which they exercised power over the living; and they believed in the existence of beings who were not and never had been human. The latter are called Vuis, and are divided into two great classes, corporeal and incorporeal. The most conspicuous amongst the first class is Qat, the legends concerning whom correspond to those which prevail among the Maories and other Polynesian people concerning Maui or Tangaroa. The brothers of Qat have all of them the name of Tangaroa, and the Vuis of the northern New Hebrides have the same name, which is also applied in Banks' Islands to stones used as fetishes or amulets. The story of Qat's disappearance from the island bears a close resemblance to that of Noah and the Flood, and has possibly been embellished since the Bible history has been made known among the natives. Of the same order of beings with Qat and his brothers, though looked upon as very inferior, are certain Vuis, having rather the nature of fairies. Some of these are called Nopitu, which come invisibly, or possess those with whom they associate themselves. The possessed are themselves called Nopitu. Such persons would lift a cocoa-nut to drink, and native shell-money would run out instead of the juice, and rattle against their teeth; they would vomit up money, or scratch and shake themselves on a mat while money would pour from their fingers. This was often seen, and believed to be the doing of a Nopitu. The story of the bringing of death into the world is remarkable, because it is told without any variation in the Solomon Islands and Banks' Islands alike. At first men never died, but when advanced in life they shed their skins like snakes or crabs, and came out in renewed youth. An old woman went to a stream to change her skin, and let the old one which she had shed float away till it caught against a stick. She then went home, where she had left her child; the child refused to recognise her, and, declaring that she was another

person, could only be pacified by the woman returning for her cast-off integument and putting it on again. From that time mankind have died. The Vuis, which are incorporeal and have nothing like a human life, have a much higher place than Qat and his brothers in the common religious system of the Banks' Islanders. They have no names, no stories are told of them, and they have no shape, but they are numerous, and are present and powerful to assist men who can communicate with them. They are very generally associated with stones, snakes, owls, and sharks. Communication with these Vuis is not in the power of all, but there is an order of priests. If a man has his stone or his snake, by means of which he supposes that he can obtain favours from his Vui, he will instruct his son or some one else to take his place. No other sacrifice than that of the shell money in common use seems to be offered in Banks' Islands. The great institutions of the Banks' Islands are the Suge and the Tamate. Neither has a religious character, nor is any superstitious practice necessarily connected with them. The Suge is a club, the house belonging to which is the most conspicuous building in every village, and is to be found wherever there is a permanent habitation; this house, or "gamal," has many compartments, each with its own oven, in accordance with the several grades in the society. To rise from one grade to another money has to be given and pigs killed. The authority of the men highest in the Suge is very considerable, and it is these persons who appear to traders and naval officers as chiefs. The Tamate is a secret society, to which entrance is obtained by payment, and the neophyte has to spend many days in the Salagoro, or sacred place; the only secret, however, is the making of the masks and hats in which the members appear in public and the way of producing the sound which is supposed to be the cry of the ghosts. The members of the great Tamate indulge in much licence. When they choose to go abroad to collect provisions for one of their feasts, the women and uninitiated are obliged to keep away from their paths. The warning voice of the Tamate is heard, and the country is shut up.

Paris

Academy of Sciences, June 21.—M. Edm. Becquerel in the chair.—The following papers were read:—On the reduction of pendulum observations to the sea-level, by M. Faye. Some deductions are here made from principles he lately enunciated.—On effects of reversal of photographic images by prolongation of the luminous action, by M. Janssen. After a certain time of exposure a less distinct negative image is had, and with continued exposure this image quite disappears, and a positive one is obtained, which may be quite as distinct as the first. This was the case, *e.g.*, in photographing the sun at Meudon, when plates that had been exposed $\frac{1}{1000}$ of a second, or even $\frac{1}{3000}$ of a second (gelatino-bromide plates) were exposed half a second or a second. The sun's disk appeared white, the spots black. Similarly, positive images of landscapes, &c., were obtained. The same spectral rays give first the negative image, then the positive.—On the heat of formation of oxides of nitrogen and of those of sulphur, by M. Berthelot. The discrepancies of former observations on oxides of sulphur are here accounted for chiefly by a simultaneous formation of several degrees of oxidation of sulphur, and perhaps even the presence of water-vapour. The author's own experiments lead to the result that $S + O_2 = SO_2$ gas liberates + 34·63.—On the luminous spectrum of water, by Dr. Huggins.—Proportion of carbonic acid in the air; reply to M. Marié-Davy, by M. Reiset.—New meteoritic mineral, with a complement of information on the fall of meteorites observed in Iowa, in May, 1879, by Prof. Lawrence Smith. The formula he now gives for the mineral (indicated at the *séance* of April 26, 1880), is $SiR + \frac{1}{2}(Si, 2R)$, or perhaps more exactly $2\ddot{S}i\acute{R} + \ddot{S}i, 2\acute{R}$, which represents 2 at. of enstatite or bronzite united to 1 at. of olivine. The name of *Peckhamite* is proposed (after Prof. Peckham). On the border of Emmel and Dickson Counties some 3,000 fragments were found within a radius of 13 km.; their total weight 30 kg. Though they had lain nearly a year under water (submerging a prairie), there was not a trace of oxidation. Prof. Smith thinks this may have been due to a thin invisible coating of silicates.—Employment of bitumen of Judæa against diseases of the vine, by M. Schefer.—Report on Mr. Peirce's memoir concerning the constant of gravity at Paris and the corrections required by old determinations of Borda and Biot. The length of the simple pendulum determined by Peirce with his own apparatus is 993·934 mm., alt. 74 m. (Biot 993·913 mm., same alt.; Borda 993·918 mm., alt. 67 m.).—On the problem of inversion, by Mr. Elliot.—On an apparatus for registering the law of motion of a projectile, either in the bore of a gun or in a resistant medium, by M. Sebert. A metallic smoked rod, of square section, is fixed in the axis of the projectile, and serves as guide to a small mass carrying a small tuning-fork furnished with two metallic points, which leave undulating traces on the blackened surface, as the projectile moves along (the prongs of the fork being liberated from a constrained state, and set vibrating, when the motion of the projectile commences). From the tracing may be deduced the velocities acquired and the accelerative force in function of the time; also the law of the pressures developed.—On the transcendants which play an important part in the theory of planetary perturbations, by M. Darboux.—On the method of Cauchy for the development of the perturbative function, by M. Trépied.—On linear differential equations with an independent variable, by M. Appell.—On certain linear differential equations of the second order, by M. Picard.—On elliptic functions, by M. Farkas.—On some modifications in the construction of the Bunsen lamp and of monochromatic lamps, by M. Terquem. There are no lateral apertures, and the air is admitted between the foot of the lamp and the bottom of the tube, which is raised somewhat (6 to 7 mm.). A cross plate divides the orifice into four parts. The temperature is found nearly uniform from the upper point of the flame to the top of the green cones, and from the centre to the circumference. (An analysis of the gases drawn off is given.) This flame is variously superior, and it gives, with sodium, *e.g.*, a much more intense monochromatic flame.—On the flow of gases, by M. Neyreneuf. —On the etherification of bromhydric acid, by M. Villiers. *Inter alia*, the limit of etherification is not equal to that corresponding to organic acids, and it rises with the temperature. Etherification ceases in mixtures containing a certain proportion of water. The limit of dilution from which etherification ceases rises with the temperature.—On the hydrate of iodide of methyl, by M. de Forcrand.—On the artificial reproduction of analcime, by M. de Schulten. The process consists in heating in a closed vessel at 180° to 190°, a solution of silicate of soda or caustic soda in presence of an aluminous glass.—Presence and special character of oyster-marls of Carnetin (Seine-et-Loire), by M. Meunier.—Prevision relative to the amount of current water in the valley of the Seine during summer and autumn of the present year, by M. Lemoine. The Seine between Paris and Rouen, with its large affluents, is expected to present one of those serious and prolonged diminutions of volume which occurred in 1863, 1868, and 1871, but no extraordinary drought.—On the geological constitution of the Isthmus of Panama, with regard to the execution of the inter-oceanic canal, by M. Bouter.

THURSDAY, JULY 8, 1880

THE TAY BRIDGE

THE Report of the Court of Inquiry appointed to investigate the circumstances of the fall of the Tay Bridge last December has now been made public. There appears to be some difference of opinion amongst the members of the court respecting the scope of the inquiry and the duties placed upon them by the Board of Trade, in consequence of which two separate reports appear together, one by Col. Yolland, Chief Government Inspector of Railways, and Mr. Barlow, President of the Institution of Civil Engineers, and the other by Mr. Rothery, the Wreck Commissioner. The former report describes in detail the design and method of erection adopted in the bridge, giving also a description of the various alterations in the plan which were rendered necessary as the work progressed.

The bridge was 3,465 yards in total length, divided into 86 spans, and it was the central portion, of 3,149 feet in length, which fell on the evening of December 28. As originally designed, this central portion was to consist of lattice girders of 200 feet span, carried by brickwork piers somewhat over 80 feet in height from high-water level, but as the river bottom turned out to be different from what was expected from the borings, and the difficulty of obtaining a secure foundation greater, eleven spans of 245 feet and two of 227 feet were substituted, and braced iron piers were adopted in the place of brickwork, as imposing a less weight on the foundations. It is these piers which at the inquiry chiefly received attention, as there can be little doubt that they were the immediate cause of the catastrophe. The process of floating out and sinking the caissons for these piers has already been described in these columns, and so successfully was this—certainly the most difficult and hazardous part of the undertaking—accomplished, that no suggestion of insufficient strength has been made, and in the Report it is stated that there is nothing to indicate any movement or settlement in the foundations of the piers which fell.

The caissons were lined with brickwork and filled with concrete, on which was built a hexagonal pier of masonry carried up to 5 feet above high-water mark. Upon this pier was built up six cast-iron columns secured by holding-down bolts to the masonry at the angles of the hexagon. The columns were made up of lengths united by flanges and bolts, and connected with each other by horizontal struts and diagonal ties. The up-stream and down-stream columns were each 18 inches in diameter, the remaining four, 15 inches; all were inclined 12 inches inwards at the top. The piers thus formed were from 81 to 83 feet in height from the top of the masonry to the under-side of the girders. The diagonal bracing consisted of flat bars attached to the columns by means of "lugs" cast on them, being secured at one extremity by a screw-bolt passing through the lugs and bar, and at the other by a strap provided with a gib and cotter for tightening up. The horizontal struts consisted of two channel-bars bolted back to back to a single lug on each column.

It will thus be seen that all vertical load must be borne entirely by the columns, and with the exception of the small transverse resistance of the latter the whole of any lateral pressure must be transmitted by the bracing.

Whether as designed the bridge would have been strong enough for its work if the materials and workmanship had been good throughout is very doubtful, but, as carried out, the evidence shows distinctly that it was not sufficiently substantial for the heavy traffic and severe gales to which it was exposed. When everything was tight and in good order the bridge, at the time of its inspection by General Hutchinson in February, 1878, showed great rigidity under the tests imposed by him, but by October of the same year so much slackness had made its appearance in the bracing that, besides the ordinary keying-up by driving the cotters, more than 100 packing-pieces about three-eighths of an inch thick had to be introduced in different parts.

Respecting the immediate cause of the accident the Court states—"In our opinion the weight of evidence points out the cross bracing and its fastening by lugs as the first part to yield." This we believe the calculations of Dr. Pole and Mr. Stewart, taken in connection with the experiments of Mr. Kirkaldy, are quite sufficient to establish. With a wind pressure of 30 lbs. to the square foot on the windward girder and train, and half this amount on the leeward girder, the stress on the tie-bar most severely strained, would be 16·8 tons, or 10·18 tons per square inch; again, with a wind pressure of 40 lbs. to the square foot the stress on the tie-bar would be 22·4 tons. Now, as Mr. Kirkaldy's experiments, made by order of the court on some of the tie-bars removed from the bridge, showed that they broke with a load of from 19 to 23 tons, and the corresponding lugs with a load of 23 to 25 tons, it is pretty certain that the ultimate strength of this part of the structure would be reached by a wind pressure of 40 lbs. to the square foot. And in addition to this more variation is to be expected in the strength of the lugs, as some at least were admitted to be of bad manufacture, and when the pier was most severely strained it would be some of the worst lugs in the lower tiers that would be the first to yield; thus the samples taken for testing would not be likely to embrace specimens of the lowest strength, as these would probably have already given way.

Again, it does not appear necessary to assume a wind pressure of 40 lbs. per square foot to ensure the destruction of the pier; the stresses above mentioned are due merely to the statical pressure, and it can hardly be denied in the face of the evidence respecting the details of the structure that there would be a great deal of motion due to backlash over and above the elastic yielding of the material. Thus a much lower pressure would produce the effects calculated for one of 40 lbs. per square foot.

The principal conclusions arrived at by the court are that there is no indication of settlement in the foundations, that the wrought iron employed was of fair strength, though not of high quality as regards toughness, that the cast iron was fairly good, that the main girders were of sufficient strength, and that the iron piers, though strong enough to sustain the vertical load, were insufficient to resist the lateral action of heavy gales from the weakness of the cross bracing and its fastenings; that the railway company did not enforce the recommendation of General Hutchinson by limiting the speed of trains over the

bridge to twenty-five miles per hour, much higher speed being frequently run; that while of opinion that the fall of the bridge was occasioned by the yielding of the cross bracing and fastenings, it might possibly have been due to the fracture of one of the outward leeward columns.

Col. Yolland and Mr. Barlow conclude by stating "that there is no requirement issued by the Board of Trade respecting wind pressure, and there does not appear to be any understood rule in the engineering profession regarding wind pressure in railway structures; and we therefore recommend that the Board of Trade should take such steps as may be necessary for the establishment of rules for that purpose."

Mr. Rothery, in his independent report, while stating that there is an entire agreement between himself and his colleagues in the conclusions arrived at from the evidence, goes further than them, and unhesitatingly apportions the blame among the different parties concerned. On the recommendation that the Board of Trade should establish rules providing for wind pressure, he differs from his colleagues, emphatically stating that it is for the engineering profession to make them, and evidently regards the superficial character of an official inspection as no great evil.

Where French engineers have long adopted 270 kilogrammes per square metre, and many English engineers, on the authority of Rankine, the equivalent 55 lbs. per square foot, while nearly the same figure is used in America, it seems strange that so much difference of opinion should be found to exist; but one thing at least is certain, that the instruments at present in use for measuring wind pressure are exceedingly crude and liable to error, and that until these are improved and much increased in number there is little chance of being on the spot when these excessive pressures occur, or of truthfully recording them when met with.

Respecting the transfer of these responsibilities to a Government Department, we believe that such apronstring policy would be fatal to the profession of the civil engineer; we would rather see the Board of Trade Inspection, which at least is formal and superficial, relaxed than any attempt made to increase its efficiency. The medical profession does not require a fatherly department to watch over its operations or give an opinion on an amputation; why then should the engineering profession? It cannot be too clearly understood that an engineering work cannot be successfully carried out by mere rule of thumb or even by the copious use of "Molesworth" or "Rankine"; each operation is to some extent a physical experiment subject to known laws, but under variable conditions. The physicist and the engineer have already to a great extent established the laws for him, but it remains for the scientific engineer to carefully watch their operation, and thus gain that practical experience which will enable him to deal with each special case as it arises.

The conclusions we draw from the evidence and report are that the design of the piers was most imperfect, cheapness appearing to be the ruling element in every detail, a cheapness too that must have been completely delusive, as any money saved in first cost would soon, in such a rickety structure, have been swallowed up in maintenance. At nearly all points an absence of consideration for small details is most apparent, indicating probably that these were intrusted to some subordinate, who failed to appreciate their importance.

It is very far from our object in this article to hold up any particular individuals to blame for this disaster, but we should like to point out on whom the responsibility should rest if such a thing should occur again.

It would be quite impracticable for the Board of Trade to exercise such supervision over the selection of the material and the execution and erection of a large work throughout its progress, as would render its certificate of any value; we believe, therefore, that the undivided responsibility should rest on the engineer. Any dishonesty on the part of the contractor or his workmen,—and we are sorry to believe this still exists in some cases,—could be easily rendered hazardous by legal penalties.

Doubtless with the keen competition of the present day things must be "cut finer" than they used to be; but while we would remove any arbitrary restrictions imposed by Government on the judgment of those who ought to be best able to appreciate the particular conditions of their own work, we should be very sorry to see the introduction of flimsy structures or reckless traffic arrangements without it being clearly understood on whom the responsibility rested in case of failure.

CAMPS IN THE CARIBBEES

Camps in the Caribbees. The Adventures of a Naturalist in the Lesser Antilles. By F. A. Ober. (Boston, U.S.: Lee and Shepherd; Edinburgh: Douglas, 1880.)

THE author of this lively and very entertaining book of travel undertook in 1876 the exploration of the Caribbees or Lesser Antilles, which islands extend over eight degrees of latitude between Porto Rico and Trinidad, connecting the Greater Antilles with the continent of South America. The islands had been hitherto little visited by naturalists, and the author made his expedition under the auspices of the Smithsonian Institution, with the especial object of collecting the birds of the group.

Around the borders of each island there is a cleared belt of fertile land, and on the coast often large villages and towns, whilst the interior is one vast forest covering wild hills and mountains. It was in the forests that the author's work lay. He took his camera into the mountains with him and photographed everything of interest which he met with, and the book is illustrated by numerous wood engravings of remarkably fine quality taken from the photographs and his sketches. About half the book, which is an octavo of 350 pages, describes adventures in the island of Dominica. Barbuda and Antigua were visited, but are not referred to at length. The account of the islands of St. Vincent, Grenada, Guadeloupe, and Martinique compose the remainder of the work, together with a catalogue of the birds of the group and descriptions of the sixteen new species of birds discovered.

Dominica was so named by Columbus, who happened to hit off the Lesser Antilles on his second voyage, because he sighted the island on a Sunday, November 3rd, 1493. The island is most beautiful. The hills are broken and ragged, seamed, furrowed, and scarred, yet covered with a luxuriant vegetation of every shade of green—purple of mango and cacao, golden of cane and lime—whilst the ridges are crowned with palms, and behind Roseau, the capital, rises Lake Mountain, four thousand feet in height, five miles distant from the town, yet seeming to overshadow it.

Mr. Ober started forthwith for the mountains, and

settled himself in a cabin in the midst of the forest amongst the mountaineer population, which is of mixed race, partly negro, partly, Carib, partly European. Here the mountaineers' children waited on him, and brought him beetles and snails and humming-birds, which they caught with birdlime. But he had to dispense with their services, for they brought him far too many things of one kind, and especially huge land-crabs as big as a man's hand. He had incautiously remarked that he should like a specimen of this crab, which abounds in the ravines and rivulet banks. "Each boy and girl in the place resolved to be the first to furnish me with the coveted crab. The consequence was that my place was soon overrun with shell-fish—ugly red and yellow crabs, as large as a man's hand, and from that to the most diminutive. One of the girls in a mischievous mood brought in a crab with a family of little ones, over a hundred, just large enough to be seen, and let them loose on the floor. Through some open window, while I was absent, some giant crab would be dropped on the floor to await my arrival. This was not done in a spirit of mischief, but from an earnest desire to aid me in my labours. For a week I could not stir without coming in contact with a shelly creature. I could not put my foot out of bed without a shudder of apprehension. Of nights I would be awakened by the rattling of ale-bottles, and arising, would discover that some crab had got thirsty in the night and had inserted a claw, which had caught in the neck of a bottle." In the afternoon the author sat looking out through the loophole of this cabin, which served as a window, and surveyed the peaceful Caribbean Sea, with the same vessels to be seen sometimes becalmed under the lee of the Caribbee Islands day after day. The sea is, however, not always placid; in the "hurricane season" it rises in its wrath. It is disturbed, however, only by a hurricane; nothing less. In the mornings and evenings he explored the beautiful forests and streambeds around his camp, gun on shoulder, and collected all he could find. Sometimes on these excursions he had merry companions, laughing girls combining Carib, French, and negro blood in their veins, and full of life and fun. Let us follow him with Marie and her friend in search of crayfish (we presume a species of Palæmon, the author unfortunately does not state). "The path is slippery, and we shall need a help from 'Marie's' hand, for the way leads up hill and over rocks wet and smooth, whilst wet leaves flap in our faces and creeping ferns and trailing plants hang on our feet as we go.

"We reach the river, the stream that flows out of the mountain lake, broad and with gravelly beach, with immense boulders as islands, and a wall of vegetation on either side that rises straight up a hundred feet. Here the two girls made into the stream in search of crayfish. The stream is broad with deep pools, and in these the crayfish lurked, looking like miniature lobsters in the clear water. We can see only the small ones, but Marie assures us that there are large ones out of sight beneath the cascades.

"Erect upon a rock she stood for a moment, then plunged head foremost into a foaming pool, disappearing from sight. A moment later rising bubbles preceded a round little head, from which hung long limp tresses; a pair of shoulders brown and bare, and round arms and little hands reaching out for a support. She had a crayfish in each hand, and another with wriggling legs in her mouth."

The following is an account of the method in which humming-birds are caught:—"Let us follow little Dan, the oldest and sharpest of the humming-bird hunters, as he goes out for birds. First he goes to a tree called the mountain-palm, which replaces the cocoa-palm in the mountains, the latter growing only along the coast. Beneath the tree are some fallen leaves fifteen feet in length; these he seizes and strips, leaving the midrib bare, a long slender stem tapering to a point. Upon this tip he places a lump of bird-lime, to make which he had collected the inspissated juice of the bread fruit and chewed it to the consistency of soft wax. Scattered over the Savanna are many clumps of flowering bushes, over whose crimson and snowy blossoms humming-birds are dashing, inserting their beaks in the honeyed corollas, after active forays resting upon some bare twig, pruning and preening their feathers. Cautiously creeping toward a bush upon which one of these little beauties is resting, the hunter extends the palm-rib with its treacherous coating of gum. The bird eyes it curiously but fearlessly as it approaches his resting-place, even pecking at it; but the next moment he is dangling helplessly, beating the air with buzzing wings in vain efforts to escape the clutches of that treacherous gum."

Mr. Ober tried hard to keep humming-birds alive, but, as usual, without success. They never survived many days. If exposed to the light they kept up a constant fluttering, until the muscles of their wings became so stiff they could not close them, but expired with the wings widely outstretched. "Every morning I would introduce into the cage a bough of fragrant lime-blossoms, at which they would all dash instantly, diving into the flowers with great eagerness. Sugar dissolved in water and diluted honey was their favourite food, and they would sip it greedily. Holding them by their feet I would place their beaks in a bottle of syrup, when they would rapidly eject their tongues and withdraw them, repeating this operation until satisfied. They never displayed fear, but would readily alight on my finger and glance fearlessly up at me, watching an opportunity, however, for escape."

The boiling lake of Dominica was visited and photographed by the author. It was remarkably quiet during his visit, showing only a slight movement in the centre. The margin showed traces of the recent subsidence of the water-level, and on the following day the water had risen again somewhat, and was more active. It appears that the ebullition must be intermittent, but Mr. Ober did not see it in full action, though the water rose further, and the disturbance and noises continued to increase. The temperature of the water was only 96° F., though Dr. Nicholls, one of the party who discovered the lake, found it at 196° F., and Mr. Prestoe, of the Botanic Gardens of Trinidad, from 180° to 190°. The author follows Mr. Prestoe in the expectation that by the widening and deepening of the outlet the lake will disappear in time, and a geyser alone remain. In a boiling spring hard by the author and his guides cooked their supper of wild yams and eggs, and, as usual, cold water for drinking was found also close at hand.

An interesting account of the Caribs of Dominica follows. They have allotted to them a reservation extending from Mahoe River to Crayfish River, a distance of about three miles along the Atlantic coast and away back into the mountains as far as they please to cultivate. Though each family has a little garden near the house, all the "*provision grounds*," where staple articles of food are grown—yams, sweet potatoes, cassava, bananas, and taro—are at a distance from the houses, some even two miles away—solitary openings made in the depths of the high woods. The Caribs are especially interesting as being the earliest American savages met with by Columbus, the original "cannibals," and the race to which Caliban and Man Friday belonged. They seem somewhat addicted to drinking now, for the author describes the old King George the Third as seen tottering towards the plantation with a sovereign he had earned in his hand to spend it in rum. A lot of drunken Caribs tried to break into the author's house one night for amusement, and not being able to do that, poked a lot of fireflies in at the cracks to light up the inside, and see for certain whether he was at home—a very neat way of lighting up an interior. The general account of the Caribs is well worth reading.

We cannot follow the author in his exciting hunt after the souffrière bird, which lives only about the crater of the island of St. Vincent. The wary bird when at last procured proved to be of a new species, *Myadestes sibilans*. In Antigua he was victimised by the well-known "jigger." "I awoke one morning with an itching of my toes, which frequent rubbing failed to allay, and examination revealed four white tumours. They were as large as peas, and in the centre of each was a little black speck. I called my boy William, who at once pronounced them jiggers." The first old negress passing was called in, and turned them out of their nests with an adroitness which showed long practice. "A few hours are sufficient to give the jigger a hiding-place, and as the sensation he causes is a rather pleasant itching only for a time, he is sometimes not discovered till a painful sore is formed."

At Dominica the author met with Dr. Miroy, a friend and correspondent of Sir Joseph Hooker, and who is endeavouring, through the aid of the Kew establishment, to re-introduce the cultivation of coffee into the island. He is cultivating Liberian coffee, in the hope that it will prove able to withstand the attacks of blight which ruined the former crops forty years ago.

In Grenada the author hunted the monkeys which abound there as at St. Kitts, having been of course introduced, and having run wild, as explained in a series of letters in NATURE some months ago. He could not, however, make up his mind to shoot one when it came to the point. The monkeys are a great pest, and do great damage to the cultivator, just as in St. Iago, Cape Verde Islands, on the other side of the Atlantic, where also they were doubtless introduced, though it is not as yet known what the species is.

The book ends with an account of an ascent of the Guadeloupe Souffrière. It is throughout entertaining and highly amusing, but the author is evidently not very deeply versed in natural history, and there is often to be noted a lack of precise information, as in the case, for example, of the crayfish, cited above. The account of the land-crabs is somewhat conflicting. At one place we read of a mother-crab, with 100 tiny young, found far up in the mountains, at another, where the author falls in with an army of land-crabs on their combined march to the sea; he tells us that they bury their eggs under the sand, where they are hatched, and soon after millions of the new-born crabs are seen quitting the shore and slowly travelling up the mountains.

The story which he tells of the habits of the huge Hercules beetle, *Dynastes hercules*, can hardly be accepted as it is by the author on the authority of his dusky guide. It is that the male beetle seizes a small branch of a tree between its enormously long nippers and buzzes round and round the branch till this is cut off, producing a knife-grinding sound, supposed by the author to be a sexual call. He heard a knife-grinding noise indeed, but he did not see the rotating beetle. We recommend the book to all our readers.

A NEW ENGLISH TEXT-BOOK OF BOTANY

An Elementary Text-book of Botany. Translated from the German of Prof. K. Prantl. Revised by S. H. Vines, M.A., D.Sc., F.L.S. (London: Sonnenschein and Allen, 1880.)

THIS text-book, we are informed in the English preface, "was written by Prof. Prantl, to meet a growing demand for a work on botany, which, while less voluminous than the well-known work of Sachs, should resemble it in its mode of treatment of the subject, and serve as an introduction *to* it." While we already have in English many text-books for students, one indeed almost professedly taking the same line as this, every teacher must have felt how inadequately they supply the needs of the class for which they have been written. Most are new editions of books written first twenty years ago or more, and suffer from the impossibility of introducing those new facts which have so deeply modified our present standpoint, without damaging the symmetry and unity of a well-written work; and others, of more recent origin, are badly compiled or over-concentrated. The book before us, avoiding these faults, will unquestionably take a high place at once; for though using Sachs as his storehouse, the author has digested the strong meat of the big book, and here provides his readers with the milk suited to their years. Moreover, the book is singularly well-balanced in all its parts, and clearly-written throughout. The translation is so flowing that no reader uninformed of the fact would guess that German was the original dress; and Mr. Vines has added to the value of the work by appending a table, in which the classification there adopted is compared with that of Bentham and Hooker.

A reference to those knotty points to which one always looks at once as tests of successful treatment has proved so satisfactory that it is with regret that we turn to the ungracious task of pointing out the deficiencies that will somehow creep into the most carefully-written books. In several points Prantl has followed Sachs too closely, so that the accounts of cell-division, of the morphology of the pollen-grain and ovule, of the growing-point of Phanerogams, are all far behind our present knowledge. Again, in the treatment of "Modes of Branching," Sachs has been followed rather than Hofmeister, who, despite his complex sentences, gives a much clearer exposition.

Thus Sachs is copied even to including the cyme in *monopodial* systems. Surely this is a contradiction in terms, and might be avoided by the use of "lateral," in contradistinction to "dichotomous." In the figures (17, 19) of uniparous cymes, Sachs, and with him Prantl, omit to mention that the diagram is taken in *plan*, a point the more important that in French and English text-books it has been usual to give such diagrams of inflorescence in *elevation*. Without noticing this, a trap is laid through which not students alone have fallen into the error of thinking that the Germans use "scorpioid" and "helicoid" in senses inverse to the usage of other botanists. Under inflorescence no mention is made of the very useful French "Cymobotrya" terminology, possibly through feelings of patriotism, with which, however, Englishmen are not concerned. The Elder is given as the example of a corymb; which term is, however, restricted by the best botanists to the corymbose *raceme*, of which the elder is not an example.

In the histology there are several not unimportant errors, probably Prantl's own. He says that the phloem contains both "phloem parenchyma" and "cambiform tissue"—is not phloem parenchyma always (primitively at least) cambiform? We are told (p. 51) that the vessels of secondary wood are "*invariably* provided with *bordered* pits;" this is far too absolute. Under collenchyma no mention is made of its commoner form, distinguished as "concave" by Vesque. Endoderm is defined as peculiar to Dicotyledons! Under "stomata" no mention is made of water-pores. The account of the structure of roots and the development of their secondary wood in Dicotyledons is hardly explicit enough, and almost demands the introduction of one or two pure diagrams; and when it is stated that rootlets arise in front of the xylem bundles of the root, mention should be made of such important exceptions as Umbellifers and Grasses.

The physiology proper is singularly well treated, though perhaps with too great a fear of detail. Thus no sufficient account is given of the *vis a fronte* and the *vis a tergo*, which lead to the movements of the rising sap.

A few little mistakes have been left uncorrected in the systematic part. The legume is stated on p. 197 to occur in "all the Leguminosæ;" and while this is modified in the account of the order on pp. 278-280, a true legume is here implicitly denied to the Cæsalpinieæ! "Replum" is given as meaning a false-dissepiment of the Crucifers, a use unauthorised by the best systematists, and inconsistent alike with its application to the lomentaceous Leguminosæ and to its Latin signification.

The figures are good, but, as usual in English editions of foreign works, poorly printed. The worse fault of separating them widely from the text they illustrate has been avoided.

Finally, despite all trouble taken by the editor, oversights will occur in a translation. Thus *Tüllen* is given in italics without its English (?) equivalent, "tyloses," and "bracteole" is given instead of the more familiar "bractlet." But these blemishes show how good is the book in which they are the worst to be found; they have been here put forward chiefly in the hope of helping the editor in the new edition which will soon be demanded; and it is with a safe conscience that we would recommend this book as the best of its kind in the English language.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Ocean Circulation

THE notice in NATURE (vol. xxii. p. 207) of the experimental researches of Professors Haughton and E. Reynolds on the coefficient of friction of water upon water, having concluded with the statement that "the authors of this research point out that these results tend to negative the theory of Dr. Carpenter that the phenomena of ocean-circulation are due to the greater height of the water at the equator as compared with that at the poles," I must be allowed to protest against being credited (or rather *dis*credited) with a doctrine which is neither expressed nor implied in anything I have written on the subject.

The doctrine which I *have* advocated is no other than that first distinctly promulgated by Lenz in 1847, and now accepted by numerous Physicists of the highest eminence, both British and Continental; viz., that besides the *horizontal* circulation produced by the action of winds on the ocean-surface, there is a *vertical* circulation of which Polar cold is the *primum mobile*, consisting of an *under*flow of Polar water (chiefly from the Antarctic area) towards and even beyond the Equatorial zone, and a complementary *upper*-flow of Equatorial water towards the Poles.

That every part of the vast Oceanic basin in free communication with either of the Polar areas is occupied, to within the range of the surface-heating produced by insolation,[1] by water which has been cooled down in one of those areas, is now one of the best-established facts of Terrestrial Physics. And those who cannot find in the excess of specific gravity imparted to sea-water by Polar cold, an adequate cause for this movement of translation, are bound to account for it in some other way.

I venture to submit to the accomplished professors of Trinity College, that laboratory experiments made to determine the friction of water upon water *at sensible velocities* can scarcely prove that when the equilibrium of a great mass of water has been disturbed, there will *not* be *any* movement of translation (however slow) for its recovery. And I would suggest to them that they should rather investigate the conditions of one of those "experiments ready prepared for us by Nature," which is constantly going on in the Baltic Straits, and of which the results have been for many years past most carefully recorded by Dr. Meyer of Kiel and his associates. Four factors are there in continually varying action, viz. (1) difference of *level* between Baltic and North Sea water; (2) difference of *salinity*; (3) difference of *temperature*, mainly due to an importation of Polar water into the Skager-rack; and (4) *surface-movement* produced by wind, which may also modify the relative levels.

I am assured by Dr. Meyer that the action of each of these factors has now been so fully determined, that the effect of any combination of them can be predicted as certainly as ordinary tidal phenomena. And of the competence of small differences in specific gravity to produce movement in great bodies of water, no one who has investigated the question on the great scale seems to have the smallest doubt. This was the unhesitating conviction of the late Mr. Froude, as the result of his numerous observations on harbours, lochs, and fiords, communicating with the sea at their mouths: for he assured me that wherever the salinity of the water at their upper end is lowered by the descent of fresh water from the land, producing a slight

[1] The researches of Prof. Forel and his associates on the Swiss lakes clearly show that in *fresh* water the heating effect of insolation is limited to about 100 feet. In *salt* water, on the other hand—as I pointed out in my Mediterranean Report—there is a *downward convection* of heat produced by the sinking of the water made heavier at the surface by saline concentration. In the Mediterranean, where this effect is limited to a part of the year, it scarcely shows itself below 100 fathoms (600 feet); but under the Equator, where it is constant, the surface-heated stratum ranges downwards to from 300 to 400 fathoms. Beneath this depth the thermometer progressively sinks in the ocean-basin generally (the thermal condition of the North Atlantic being altogether exceptional) from 40° to 33° or thereabouts; whilst in the Mediterranean, to the deeper part of whose basin the Polar underflow has no access, the thermometer shows a uniform temperature of from 54° to 56° (according to the locality) from the surface-heated stratum to the deepest bottom (2,000 fathoms).

surface outflow, he could trace an underflow of sea-water up the channel; and this he could attribute to nothing else than the slight excess of *downward* and therefore *lateral* pressure in the *outside* column, depending on the continually-maintained reduction in the mean salinity of the *inside* column, which more than compensated for any slight excess in its level.

WILLIAM B. CARPENTER

The Freshwater Medusa

IN NATURE (vol. xxii. p. 190) Prof. Lankester refers to a statement of mine in the preceding number, that I had arranged with Mr. Sowerby some methods of observation from which I hoped to obtain data for the determination of important points regarding the development of the freshwater Medusa, and expresses a desire to be informed as to the nature of the proposed methods.

The obvious and only practicable course to be adopted with this view was arranged with Mr. Sowerby by Mr. Busk and myself, and consisted in the separation of specimens from the Victoria tank and their confinement in glass jars, which, in order to secure a continuance of the necessary temperature conditions, were to be retained in the same house with the tank in which the Medusa had shown itself. The examination from time to time of these jars would probably bring to light facts having a direct bearing on the development of the animal. This method of observation, indeed, is so obvious that it must have occurred to any one engaged in the investigation it was designed to aid.

Prof. Lankester now says that Mr. Sowerby informs him that he had undertaken no experiments except such as had been carried out at his request; but as it seems that these are identical with those proposed by Mr. Busk and myself, nothing has been thereby lost.

Residing at a distance from London, my opportunities of studying the life-history of the Medusa are at this moment comparatively few. Prof. Lankester, however, being on the spot, and having an unlimited supply of subjects for investigation, will doubtless avail himself of the advantage thus afforded, and will render our knowledge of this remarkable little animal more complete than would otherwise have been possible.

Prof. Lankester refers to the difference of opinion between himself and me, and promises to bring proofs of his own views. When these proofs are offered I shall gladly accept them. My desire is that no previous expression of opinion shall blind me to evidence in favour of a contrary position. The only important points, however, on which my conclusions have been absolutely at variance with those of Prof. Lankester are the presence of a circular canal and the perviousness of the distal extremities of the radial canals. With regard to these there cannot in my opinion be the slightest doubt.

The nature of the marginal bodies is also a point of much importance in this investigation, but I have expressed only a conditional opinion with regard to it. While Prof. Lankester considered these bodies as undoubtedly tentacular, I held that the evidence afforded by adult and by comparatively young specimens is in favour of their velar origin; but at the same time I stated that this point cannot be decided without the evidence obtained from development.

I also drew attention to the remarkable attachment of the tentacles, whose adnate basal portion occupies exactly the position of the *peronia* in the Narcomedusæ and Trachomedusæ, but I failed to find evidence of the presence of true peronia as described by Prof. Lankester, who now admits that the peronia while present are rudimental.

The other points, namely those which concern the systematic position of the Medusa, are necessarily only hypothetical. It appeared to me that while there are certain features in the structure of the adult Medusa which point towards the Trachomedusæ, there are others which connect it with the Leptomedusæ, to which on the whole it seemed to be more closely allied, though holding a position intermediate between the two; but I regarded the data in our possession as insufficient for the final determination of this point, which can be absolutely settled by the study of development alone.

Prof. Lankester promises details of his observations in this month's number of the *Quarterly Journal of Microscopic Science*, and I look forward to what I doubt not will be a valuable contribution to hydroid zoology.

As to the name of the Medusa, Prof. Lankester, while abandoning his generic name in favour of mine, declares it to be his intention to retain his own specific name for the animal. This is to me a matter of complete indifference. Science can gain nothing from personal contention about names, and the time so occupied might with far greater advantage be devoted to more useful and lasting work.

J. ALLMAN

On the Simplest Continuous Manifold of Two Dimensions and of Finite Extent

SO far as I am concerned Mr. Frankland answers too soon (p. 170), for I am sorry to say I have not read Klein in the meantime. Therefore my reply is provisional. A hint was given of Mr. Frankland's explanation by Mr. Newcomb in a phrase quoted by Mr. Halsted (*American Journ. of Math.*, I. iii. 275, paper on the bibliography of hyperspace, &c.): "The first elements of complex functions imply that a line can change direction without passing through infinity or zero." We do not require even the first elements of complex functions to tell us that we can get to the other side of a point without passing through it, provided we can go round it. But the question was not whether "a line" simply could be thus reversed, but whether it could be so with the geodetic perpendicular in question described in a uniform continuous manifold of two dimensions. Mr. Frankland's explanation expressly takes account of a third dimension. It supposes the moving line to generate a sort of skew helicoid about the fixed line to which it is perpendicular. But how can even initial portions of successive generators be in the same plane, Euclidean or other? This point may seem incidental, but I think it is essential, so I omit further questions.

Somewhere in his "Dynamic" Clifford says that Klein's double surface is a sphere in which opposite points are considered as one. In this light the mystery disappears. There are two perpendiculars: considered as one they never change sign; because, considered as two, they periodically exchange signs. But if opposite points do not coincide, they may be "one," but they are not one point; if they do, is the manifold they compose a surface? Mr. Frankland has not called it a surface: but is it continuous?

There is a very well-known manifold which obviously obeys the laws worked out by Mr. Frankland and Mr. Newcomb, a system of straight lines, not vectors, through a common point; or, reciprocally, a system of planes. To measure of curvature answers density; if this is constant, the geodetic distance from a point to a geodetic line is represented by the angle between a straight line and a plane.

It may be worth while to note one or two oversights in the writing or printing of Mr. Frankland's letter. For $\frac{1}{2}l\sqrt{-1}$ we ought to have an expression involving the angle between the geodetics. The sentence "If a being," &c., is a quotation, and the last word should be "position," not "poise."

Both Mr. Newcomb and Mr. Frankland understand my intention as more negative than it was. I said (xv. 547) "it could hardly fail to be instructive if Mr. Frankland would explain," &c. Probably I underrated the difficulty, in this Euclidean world, of making it clear that one means just what one says.

C. J. MONRO

Hadley, June 29

A Fourth State of Matter

IT seems to me that Mr. Tolver Preston in his letter on the above to NATURE (vol. xxii. p. 192) has somewhat overlooked the context in the objections he urges against Mr. Crookes's remark that "an isolated molecule is an inconceivable entity." It is plain that Mr. Crookes meant this statement to apply to the *quality*, not the *existence* of a molecule, and granting Mr. Crookes's premisses regarding the constitution of matter, it appears a very fair deduction; since if the three states of matter (as we know it), viz., solid, liquid, and gas, owe their different *qualities* merely to different modes of motion of the ultimate molecules, it is quite conceivable as well as logical to suppose that the latter have a nature totally unlike that of the effects of their motion, and therefore inconceivable to us by reason of its dissimilarity to anything of which we at present possess any knowledge.

Again, with reference to the remark, "solid it cannot be,"

which Mr. Preston calls in question, it would be manifestly illogical on his premisses for Mr. Crookes to regard the isolated molecule as a solid, even though, according to Mr. Preston, it may possibly possess certain properties in common with what we call solids, for solidity, according to Mr. Crookes, being "merely the effect on our senses of the motion of the discrete molecules among themselves," it would be exceedingly arbitrary to ascribe to the molecules themselves a quality which, as we *commonly* know it, is simply an *effect* of their motion.

July 3 E. DOUGLAS ARCHIBALD

Minerva Ornaments

I NOTICE that a correspondent writing from America expresses his scepticism as to the figural character of certain stone objects in Dr. Schliemann's collection at South Kensington. Judging from the analogy of similar objects found in America, he pronounces them to be "net-sinkers" and not idols. Whatever, however, may be the nature of the American objects, I think there can be but little doubt that Dr. Schliemann is right in considering the objects discovered by him at Hissarlik to be rude representations of a deity. At first sight they certainly have but little resemblance to anything of the sort, but a careful examination shows that several are marked with the rude delineation of a human face—or, as Dr. Schliemann believes, of an owl's face —as well as of a triple necklace, and sometimes also the characteristics of a woman. Occasionally the hair is represented on the back of the head by straight lines. The delineation is sometimes incised, sometimes painted, though the paint is mostly worn off. As the marked objects are of the same shape as the unmarked ones, we can have no hesitation in inferring that both were intended for the same purpose. A. H. SAYCE

Arthur Young's Travels in France

A FEW months ago my friend Mr. F. F. Tuckett, of Bristol, drew my attention to a passage in Arthur Young's Travels in France, published in 1792, narrating a visit to Lavoisier and to a certain M. Lomond, the inventor of an electric telegraph, which in some points anticipated that of Ronalds. The mention of Lomond's name in a historical list of telegraphic inventors recently published by your contemporary, the *Scientific American*, induces me to send you the inclosed extract as likely to be of interest to the readers of NATURE. S. P. THOMPSON

Univ. Coll., Bristol, June 18

"The 16th.—To M. Lavoisier by appointment. Madame Lavoisier, a lively, sensible, scientific lady, had prepared a *déjeuné Anglois* of tea and coffee, but her conversation on Mr. Kirwan's Essay on Phlogiston, which she is translating from the English, and on other subjects which a woman of understanding, that works with her husband in his laboratory, knows how to adorn, was the best repast. That apartment, the operations of which have been rendered so interesting to the philosophical world, I had pleasure in viewing. In the apparatus for aërial experiments nothing makes so great a figure as the machine for burning inflammable and vital air, to make or deposit water; it is a splendid machine.

"Three vessels are held in suspension with indexes for marking the immediate variations of their weights; two, that are as large as half-hogsheads, contain the one inflammable, the other the vital air, and a tube of communication passes to the third, where the two airs unite and burn; by contrivances, too complex to describe without plates, the loss of weight of the two airs, as indicated by their respective balances, equal at every moment to the gain in the third vessel from the formation or deposition of water, it not being yet ascertained whether the water be actually made or deposited. If accurate (of which I must confess I have little conception) it is a noble machine. Mons. Lavoisier, when the structure of it was commenced, said, 'Mais oui, monsieur, et même par un artiste François!' with an accent of voice that admitted their general inferiority to ours. It is well known that we have a considerable exportation of mathematical and other curious instruments to every part of Europe, and to France among the rest. Nor is this new, for the apparatus with which the French Academicians measured a degree in the polar circle was made by Mr. George Graham. Another engine Mons. Lavoisier showed us was an electrical apparatus inclosed in a balloon, for trying electrical experiments in any sort of air. His pond of quicksilver is considerable, containing 250 lbs., and his water apparatus is great, but his furnace did not seem so well calculated for the higher degrees of heat as some others I have seen. I was glad to find this gentleman splendidly lodged and with every appearance of a man of considerable fortune. This ever gives one pleasure: the employments of a state can never be in better hands than of men who thus apply the superfluity of their wealth. From the use that is generally made of money, one would think it the assistance of all others of the least consequence in affecting any business truly useful to mankind, many of the great discoveries that have enlarged the horizon of science having been in this respect the result of means seemingly inadequate to the end: the energetic exertions of ardent minds, bursting from obscurity, and breaking the bonds inflicted by poverty, perhaps by distress.

"To the 'Hotel des Invalids,' the major of which establishment had the goodness to show the whole of it. In the evening to Mons. Lomond, a very ingenious and inventive mechanic, who has made an improvement of the jenny for spinning cotton. Common machines are said to make too hard a thread for certain fabrics, but this forms it loose and spongy.

"In electricity he has made a remarkable discovery: you write two or three words on a paper, he takes it into a room and turns a machine inclosed in a cylindrical case, at the top of which is an electrometer, a fine small pith ball; a wire connects with a similar cylinder and electrometer in a distant apartment; and his wife, by remarking the corresponding motions of the ball, writes down the words they indicate: from which it appears he has found an alphabet of motions. As the length of the wire makes no difference in the effect, a correspondence might be carried on at a distance—within and without a besieged town, for instance, or for a purpose much more worthy, and a thousand times more harmless, between two lovers prohibited or prevented from any better connection.

"Whatever the use may be, the invention is beautiful. Mons. Lomond has many other curious machines, all the entire work of his own hands. Mechanical invention seems to be in him a natural propensity." ("Travels during the Years 1787, 1788, and 1789," by Arthur Young, Esq., F.R.S. Vol. i. p. 64.)

"Saxifraga umbrosa" adorned with Brilliant Colours by the Selection of Syrphidæ

AMONG Diptera the most assiduous visitors of flowers are certain Syrphidæ, which, elegantly coloured themselves, are fond of splendid flower-colours, and, before eating pollen or sucking nectar, like to stop a while, hovering free in the air, in front of their favourites, apparently fascinated, or at least delighted, by the brilliancy of their colours. Thus I repeatedly observed *Syrphus balteatus* hovering before the flowers of *Verbascum nigrum*, often *Melanostoma mellina*, and *Ascia podagrica* before *Veronica chamædrys*; in the Alps the lank *Sphegina clunipes* before *Saxifraga rotundifolia*, and in my garden *Ascia podagrica* before *Saxifraga umbrosa*.

Of *Verbascum nigrum* the main fertilisers are humble-bees, Diptera co-operating only in a subordinate degree; in the case of the three other species, on the contrary, the above-named Syrphidæ are such frequent visitors and cross-fertilisers that we may safely conclude that it is by their selection of elegantly-coloured varieties that these flowers have acquired their beautiful peculiarity. Hence, in order to estimate the colour-sense of these Syrphidæ, it is worth while to consider what colour-combinations they have been able to produce by their selection.

Saxifraga umbrosa being, as far as hitherto known, their finest masterpiece, we may in the first place look at the variegated decoration of this species. Its snow-white petals are adorned with coloured spots, which in size and intensity of light gradually decrease from the base of the petals towards their extremity. Indeed, nearest to their base, within the first third of their length, there is a large irregular spot of an intense yellow; about the middle of their length there follows a narrower cross band of red colour, vermilion towards the base, intensely pink towards the outside, not reaching the margins of the petals, sometimes dissolved into several separate spots; lastly, beyond the middle of the length of the petals there are three to eight smaller roundish spots of a paler violet-pink colour.

The flowers of *Veronica chamædrys* prove that also gay blue colours are perceived and selected by Ascia.

Lippstadt, Germany HERMANN MÜLLER

Dilatation of the Iris

In addition to the method of observation mentioned by Mr. Ackroyd in his photometric proposal (NATURE, vol. xxi. p. 627) I may mention that the variations of the diameter of the pupil are very beautifully observed by a pair of punctures in a screen over the eye. In fact long ago I used this as a means of observing the absolute diameter of the pupil, subject to a small unexamined constant error.

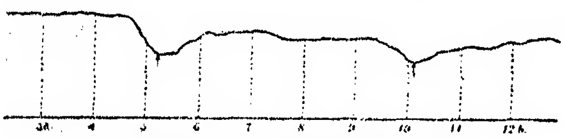
By pricking a row of holes in a card at distances of ·06, ·07, ·08 . . . . ·25 inch, and placing this close over the eye, the diameter is observed by sliding the card until two of the holes are found at such a distance that their edges appear to touch. The opening of the other eye, or the slightest disturbance of light, produces an apparent alteration in the sizes of the disks of light, so that their edges recede or overlap; and a fresh pair of holes may be found showing the altered diameter of the pupil.

Thus (1) the extreme diameters of the pupil were found to be ·07 (? ·06) and ·25 inch; (2) the diameter is rapidly variable at will, *without any alteration of stimulus*, even as much as from ·13 to ·19 inch; (3) the sympathetic motion takes ·4 or ·5 second to be produced when the other eye is exposed to light. Many similar interesting questions may be examined by this simple instrument; for which purpose I inclose a sample card for editorial trial. W. M. F. P.

Comparative Curves in Terrestrial Magnetism

MONSIEUR,—En séquence à la intéressante communication de Rev. S. J. Perry de l'Observatoire de Stonyhurst, je vous prie d'additioner les suivants renseignements sur la même perturbation magnétique de 17 mars passé, d'après la courbe du déclinographe de l'Observatoire du Infant D. Luiz, à Lisbonne.

La différence entre le maximum et le premier minimum à 5h. 49,5m. G.M.T. est de 13',9 (un tiers du mouvement à Stonyhurst), et entre le même maximum et le 2e minimum à



Declinographe 17 Mars, 1880 (Lisbonne M.T.).

10h. 45m. G.M.T. est un peu plus grande 16',2, le contraire qu'on voit à Vienne et Stonyhurst.

Il est digne aussi de remarque que le temps du 1er minimum ne s'accorde avec le temps à Stonyhurst et Vienne, pendant que le temps du second est de parfait accord.

La longitude de cet Observatoire est + 36m. 35s. G. Je vous envoie la copie de la courbe.

Agréez, Monsieur, l'assurance de ma haute considération.

Lisbonne, 21 juin 1880 J. CAPELLO

Effects of Lightning on Trees

YOUR note in NATURE, vol. xxii. p. 204, on the recent thunderstorm at Geneva induces me to send you a note on a tree struck by lightning in Stoneleigh Park during a severe storm on last Thursday week (June 24). The tree was a fine oak about forty feet high, and the lightning seemed to have struck not among the smaller branches at the top, but about two-thirds of the way up the main trunk, just where several of the larger branches came off from the stem. From this point to the ground the bark had been rent off along a strip about three inches wide, and through the whole length the wood beneath the bark had been gauged out as if by a carpenter's tool, the groove made being about an inch wide and deep. The curious fact of the tree being struck apparently among the branches at once suggested to me that the electricity must have travelled, without visible effect, through the upper branches, and only produced disruption of the wood when the current was strengthened by the combination of a great number of separate streams. I had forgotten that this was Prof. Colladon's theory of electric discharge, but am glad to be able to give it the support of this observation.

Rugby, July 3 L. CUMMING

Iron and Hydrogen

IN the description given a few weeks back of the experiments of Prof. Hughes, the fact was demonstrated that iron wire in contact with dilute acids becomes brittle, and at the same time takes up hydrogen.

There are one or two points of great interest that many, perhaps, besides myself, would like to know more about.

Thus, at the same time the iron becomes brittle, does it also become harder?

This leads one to speculate on the facts illustrated in the hardening and tempering processes of steel.

We know that such liquids as water, weak acid, oil, &c., which are used as baths in which the heated metal is quenched, are all decomposable by iron and other metals at a high temperature, the result being the liberation of hydrogen, &c. Now is it not probable that this liberation of hydrogen is really the essential element in the physical change produced in the hardened steel?—that is to say, that the steel absorbs, or perhaps becomes alloyed with the nascent hydrogen in contact with its surface, thus rendering it intensely hard?

Prof. Hughes has pointed out that a red heat entirely dissipates the hydrogen from the iron wire, which returns to its normal state.

This perhaps will explain the process of tempering by supposing that a certain proportion of the (hardness-rendering) hydrogen is driven off according to the temperature reached, as shown in the well-known shades of colour seen on the surface —that is to say, the hardness is proportionate to the contained hydrogen, such as that many other metals become very hard or soft by being alloyed as zinc and copper in brass, tin and copper in bronze, &c.

This is supported by the fact that one of the most successful processes of hardening depends on the use of a quenching-bath of dilute sulphuric acid. This would be explained by the greater ease with which acidulated water is decomposed by iron, and therefore a larger bulk of the nascent hydrogen liberated on its surface could be absorbed by the metal.

The carbon in steel probably only plays the part of a go-between in rendering the absorption of hydrogen more facile. There is a fact that also supports this, namely, if unhardened steel is dissolved in HCl the carbon is left in the form of graphite scales, whereas after hardening, if treated with the acid in the same manner, the residue is found to consist of a liquid hydrocarbon, thus showing the presence of hydrogen in the metal.

These points I should like to have been able to confirm or refute for myself; but not having the required time or apparatus, I leave it with the hope that some one possessing those advantages will settle these questions. H. J. JOHNSTON-LAVIS

Naples

"Coronella lævis"

IN NATURE, vol. xxii. p. 156, the presentation is announced of two specimens of *Coronella lævis* (British) to the Zoological Society. I have known so many persons doubt the existence of the *Coronella* in the New Forest that I should feel greatly obliged to any of your correspondents who would give me some information as to its history, whether it has been introduced, or is really indigenous. H. KING

[Mr. Sclater tells us that he has no doubt that the smooth snake is indigenous to the British Islands, although it was overlooked for many years. The first living example received by the Zoological Society was in August, 1862, presented by Mr. Fenton, having been obtained in the neighbourhood of Sandhurst. Since then nearly twenty specimens have been received, chiefly from the New Forest and neighbourhood of Bournemouth. See Mr. Cooke's excellent little volume, "Our Reptiles" (London, 1865), for a full account of this species of snake. —ED.]

Recall of Appearance of Books, &c.

I HAVE only to-day been able to read the back numbers of NATURE for the past two or three months, and hence have only now seen Mr. Ernst's letter in your issue of April 29 last.

His power of recalling the appearance of books I know is possessed by others. I have a very large and still increasing library, but there is hardly a volume, or indeed a tract, the appearance and condition of which does not at once present itself to my mind if occasion to use it should arise. Further, being engaged in the compilation of a work some years since, wherein many references to other books were necessary, I used,

when away from home (as was frequently the case) to write and indicate not simply in what part of the library the book would be found, but in what portion of the volume, and almost always whether on the left or right hand page, any given passage required would be found.

Of late years I have found it desirable to rebind my tracts in something of a uniform manner. Their external individuality is thus destroyed, but the aspect of their title-pages and the location of particular passages of the contents remain as fresh as ever. CORNELIUS WALFORD

London, June 24

Stags' Horns

WITH further reference to the above question I have pleasure in inclosing a letter received to-day from the head keeper at Bradgate Park, near Leicester, where both red and fallow deer are kept.

I may add that I saw at the end of July last, near the head of Loch Eribol, in Sunderland, a quantity of stags' horns in a gipsy encampment, which I supposed had been collected for sale by that curious fraternity. HERBERT ELLIS

62, New Walk, Leicester

"To HERBERT ELLIS, ESQ.

"*Bradgate Park, 22nd June*, 1880

"DEAR SIR,—In answer to yours of the 19th inst. respecting what becomes of the stags' horns after being shed, I beg to say they are regularly collected and sold. But there is not the slightest doubt of their eating each other's horns. I have myself seen several cases where both brow antlers and the top points have been gnawed off. I have also seen Scotch heads that have been quite spoiled by the tines having been gnawed, which must have been done after the horn had become hard, and whilst the animal was living. I am, sir, yours respectfully,

"C. OVERTON"

Cup and Ring Stones

MANY of the markings mentioned by Mr. Middleton are hollows made by rain, or rather deepened by rain-water holding many low organisms in hollows, on the upper surfaces of exposed grit stones; overflow from these accounts for the groove or spout noticed at the margin of some of them. They are to be seen on the stones erected near Boroughbridge, and speak to the length of time these stones must have been raised into their present position. W. S.

June 21

Diatoms in the London Clay

To enable me to determine the exact extent of the diatomaceous band in the London clay, I am anxious to obtain information of any wells in progress, or in contemplation, anywhere in the London Basins, *west* and *north* of London. With the help of some of your readers I have no doubt that I shall shortly be able to show that the one referred to is co-extensive with the London clay. The details I wish for are:—

1. Locality of well.
2. If begun, the depth attained.

I shall also be glad to hear of any railway cuttings now being made in the same area. W. H. SHRUBSOLE

WATER SUPPLY

AMONG the improvements in sanitary matters that this generation has witnessed not one ranks higher than the settled and still growing conviction of the importance of a pure water supply, and nowhere are the various aspects of the question more keenly debated and considered than in the Metropolis at the present time.

At a discussion at a recent meeting of the Chemical Society there seems to have been some doubt thrown on the conclusions arrived at by chemists in determining the wholesomeness of a water by no less an authority than Prof. Huxley, and it may be well to inquire how far his allegations are borne out by facts.

In the earlier days of the history of chemistry, as was to be expected, the processes adopted in the analysis of water were crude in the extreme, and the quaint ideas promulgated in the treatises then published are not a little amusing. Gradually, however, and especially during the last few years, the methods of analysis have improved, and although, judging by the wide diversities of opinion that exist as to what may or may not be pronounced a water sufficiently pure for drinking purposes, the subject cannot yet be said to have arrived at a stage completely satisfactory; still, so far as the purely chemical evidence is concerned, it would seem to be able to furnish results which are sufficiently exact for all practical purposes. The operations involved are among the simplest and easiest the chemist has to perform, and consequently it is not the data furnished by analysis that are called in question, but the conclusions drawn from them.

Persons interested in sanitary questions, but who have no special knowledge of the difficulties that beset the forming a correct judgment as to the wholesomeness of water, are apt to express themselves as scandalised, and it must be confessed with some show of reason, that it should be possible there should be so little agreement amongst those who are looked up to as authorities on such matters.

This disagreement, however, is more or less inevitable in the present state of our knowledge, and is largely due to the intricacy of some of the problems involved in the question, which is by no means a simple chemical one.

The debatable ground is the nature and estimation of organic matter and the amount of significance that should be attached to the presence of oxidised nitrogen compounds.

Organic matter may be of animal or vegetable origin, the former being dangerous and the latter much less so, if indeed it be not altogether innocuous. To distinguish between the two kinds is therefore all important; but unfortunately it is impossible directly to do this, as both animals and vegetables yield albuminoïd matters, which are, chemically speaking, practically identical in composition.

Of the various processes for the estimation of organic matter there are three that are in general use. One, the oldest, known as the permanganate process, finds its advocate in the present day in Dr. Tidy, and consists in measuring the organic matter by the quantity of oxygen required to oxidise it. Another, originated by Prof. Wanklyn, and which he calls the albuminoid-ammonia process, consists in decomposing the organic matter by an alkaline solution of potassium permanganate, and taking the resulting ammonia as the measure of the organic matter. The third process, the one employed in the laboratory of the Rivers Pollution Commissioners and advocated by Dr. Frankland, its originator, estimates the organic carbon and nitrogen separately.

A good deal may be said in favour of all these processes, as affording a rough estimation of the quantity of organic matter, but none of them can be relied upon as giving any indication of its nature, *i.e.*, as to whether it is dangerous or not; and yet it is the almost invariable custom to judge of a water by the quantity of organic matter it contains, no matter what its origin, and a variation of two or three times a given amount is held to make the difference between a good and bad water.

It was to this point that Prof. Huxley especially addressed himself in his remarks already referred to. He gave it as his opinion, speaking as a biologist, "that a water may be as pure as can be as regards chemical analysis, and yet, as regards the human body, be as deadly as prussic acid, and on the other hand may be chemically gross and yet do no harm to any one." "I am aware," said he, "that chemists may consider this as a terrible conclusion, but it is true, and if the public are

guided by percentages alone they may often be led astray. The real value of a determination of the quantity of organic impurity in a water is, that by it a very shrewd notion can be obtained as to what has had access to that water."

However startling these statements may be to those who judge of the wholesomeness of a water by the amount of organic matter it may contain, we believe it to be none the less an accurate description of facts. It is within our knowledge that some of our most wholesome supplies sometimes contain an excess of organic matter, and that the waters which give rise to typhoid fever and other hardly less serious disorders are frequently just those which contain the least, the difference of course being that in the one case the organic matter is innocuous, in the other deadly.

Since, then, chemical analysis fails entirely to distinguish between these two kinds of matter, it may be thought to be a work of supererogation to have recourse to it at all. Not so, however, for what analysis fails to do directly it can to a large extent do indirectly. Organic matter in solution in water is more or less prone to oxidation, the highly putrescible matter of sewage being most so, and that derived from vegetation very much less so. Hence it follows that one would expect to find the oxidised nitrogen compounds in greater excess in the one case than in the other, and as a matter of fact that is just what we do find. Almost invariably, in all waters of acknowledged wholesomeness, the quantity of nitrates never exceeds a certain small amount, whereas in waters, such as polluted well and spring waters, that have given rise to illness, the oxidised nitrogen compounds, with other accompaniments of sewage, are to be found in excess. By means then of these oxidised nitrogen compounds we get collateral evidence throwing light on the nature and probable source of the contamination of which a mere percentage estimation of organic matter would fail to give the slightest indication.

The mistake has been hitherto that the discussion has been narrowed by looking at the question almost entirely from a chemist's point of view. It is, however, to the biologist that we must look chiefly for the future elucidation of the subject, and he has a field of the widest range, embracing much untrodden ground, for his investigations.

Putting on one side the specific poisons which through the medium of water are able each to generate, after its kind, diseases such as typhoid fever, it is highly probable, judging from what has already been proved to take place in analogous cases, that dangerous organic matter is not poisonous as such, but acts by affording the pabulum for organisms which are able to set up putrefactive changes in the blood of the person drinking polluted water. Even the conversion of organic matter into nitrates is not a mere chemical process of oxidation, since we now know that the oxidation only takes place by the help of a distinct ferment.

In the inquiry as to how far organic matter is destroyed in rivers, it is clearly insufficient to rely upon laboratory experiments in which diluted sewage is exposed only to the oxidising influence of air. This is entirely to ignore the agency of vegetation and of the vast army of organisms, identical with or allied to bacteria, which, being endowed with various functions of reorganisation, convert the carbon and nitrogen of organic matter into simpler inorganic compounds, these in turn to become the food of the more highly organised aquatic vegetation.

Whilst therefore duly recognising the practical help that chemistry can afford in the more limited scope that properly belongs to it, we trust, in the interest of sanitary science, that the enunciation of the views of so distinguished a biologist as Prof. Huxley may have their due weight with those to whom these questions are ordinarily referred, and will tend to promote a better understanding and more solid ground for agreement than has up to the present seemed possible.

CHARLES EKIN

THREE YEARS' EXPERIMENTING IN MENSURATIONAL SPECTROSCOPY[1]

BY A NEW HAND THEREAT

II.

The Whole Solar Spectrum.—Could an observer, who had once made close acquaintance with the glories of symmetry resident in great A of the solar spectrum, when seen in the brightness of a southern noon-day, under a dispersion of 33° and magnifying power of 10, ever remain content therewith?

Never! if a particle of soul belonged to him! for he would be imperiously constrained from that moment to feel that he must see the whole solar spectrum as it is given forth effulgently to the denizens of the south by a nearly zenith sun, before he died; or to what purpose would he have lived in a sun-illumined world?

Out, therefore, once more to Lisbon the experimenter and his Wife went in 1878, with the important assistance again of the Pacific Steam Navigation Company of Liverpool; but now, armed with a rather different apparatus. There was indeed the same heliostat and there were all the prisms belonging to the aurora spectroscope; but instead of each of them being looked through singly and successively, they were now used all together, set out in a curvilinear line several feet long on a large table, and looked through all at once; with telescope and collimator each 32 inches in focal length; with magnifying power of 20, and a further prismatic method supplanting the usual employment of coloured glasses to prevent false glare in the field of view; and then what a new world was opened up to behold and admire!

Lines multiplied on lines and in a perfection of finish and refinement, sometimes of infinite thinness, sometimes remarkable power; and the classic fields of those more refrangible portions of the spectrum where the great spectroscopists of the age, Kirchhoff and Secchi, Lockyer and Janssen, Huggins and Young, have chiefly gained their laurels, as expounders of the constitution of the sun, were surveyed with respect and all admiration; but first, foremost, and beyond everything else, were the glories of the illimitable depths of solar colour; colour, the best leading index that has ever been invented yet, to simplify and facilitate the description of all spectrum place.

After having got completely rid of those usual attendant impurities in solar spectroscoping, viz., chemically coloured glasses used as shades, the large dispersions now employed enhanced rather than dulled the solar colours; raised one's ideal of what colour in light can be, and gave, through near fifty gradations, a definite and ever-memorable colour-characterisation to as many portions of the whole spectrum.

In presence of *such* solar colours, it seemed to be a wilful ignoring of one's best and plainest faculties to speak of the spectrum colours as being only 3, or 5, or even 7. They might indeed be rather spoken of as next to infinite in number; or rather still, as being just so many as there are easily perceptible differences of spectral place; *but* for that law of locomotion of colour-bands within certain limits, already discovered by the experimenter in his absorption spectra, and found equally applicable to the solar spectrum. Confining therefore the number of colours to something which should give each of them a breadth, not likely to be overpassed by the locomotive effects + and − on their boundaries, the following table of fifteen spectral colours was prepared after much discussion and criticism of each individual member of it:—

[1] Continued from p. 195.

General Distinctions.	Particular Colours.	Wave-Number Spectral Place, normally. Extends from	Reaches to	Solar Lines within those Limits of Place.	Chemical Flame, and Electric Spark, Lines within the same Limits.
Red end of Spectrum.	Ultra-Red.	25,000	30,000	X.	—
	Crimson-Red.	30,000	34,000	Y and A.	Rubidium *x* and Potassium *a*.
	RED.	34,000	37,000	Little *a* and great B.	Lithium *a*, nearly.
	Scarlet-Red.	37,000	39,000	Great C.	Scarlet Hydrogen Line.
	Light-Red.	39,000	40,000	*c*′ and *a* Band.	Light-Red Oxygen.
Middle of Spectrum.	Orange.	40,000	42,000	*a* Band and Rain-Band.	Carbo-Hydrogen's Orange Band, and chief Oxygen Line.
	Yellow.	42,000	44,000	D.	Sodium *a*.
	CITRON.	44,000	47,000	Aurora's chief Line.	Carbo-Hydrogen's Citron Band of Lines.
	Green.	47,000	51,000	E and little *b*.	Thallium *a* and C.-h.'s Green-Giant Line.
	Glaucous.	51,000	55,000	Little *c* and F.	Glaucous Hydrogen.
Violet end of Spectrum.	Blue.	55,000	57,000	Little *d*.	Cæsium *a* and *β*.
	Indigo.	57,000	58,000	Little *e* and little *f*.	Indigo Nitrogen Band.
	VIOLET.	58,000	61,000	Great G and little *g*.	Violet-Hydrogen Line.
	Lavender.	61,000	65,000	Little *h* and great H^1 and H^2.	Lavender-Hydrogen Line.
	Gray.	65,000	70,000	—	—

The colour question settled, then came the measurement of the places of the lines seen therein and amongst. Each day the rather ragged train of some simple, some compound, prisms was set to minimum deviation for each of them in the part of the spectrum concerned, and from 100 to 200 or more lines per day were securely recorded day after day; until at last, after that long and laborious journey through all the colours and all the lines, not omitting to chronicle in appearance, as well as measured place, a single one amongst 2,000, at last, like huge volcanoes throwing out pillars of black smoke streaked with vertical lines, the overpowering forms of H^1 and H^2 hove in sight, and formed a fitting balance as well as contrast in the violet to great A and its rhythmical predecessors in the red.

But long, long before soundings were touched in the appearance of these two smoky giants, certain questions had to be wrestled with touching the terms in which all spectral places should be measured and published.

Full of desire to contribute data for theorists, the experimenter had indulged in the prospect of recording all line-places in terms of wave-lengths; and had even made his versatile, Robinson Crusoe sort of solar spectroscope, read its scales in numbers increasing as the wave-lengths of light do, from the violet towards the red end of the spectrum; and also caused it to present the violet end towards the left, and the red towards the right hand, as with most of his predecessor's maps employing wave-lengths. Further still, as he found it expedient to compare the solar spectral lines he was observing each day with the best maps and photographs he could collect, he applied a wave-length scale to each of them, made them all turn their violet ends leftward, and then tried to trace each line visible in the telescope through all its previous renderings or omissions by previous observers.

But oh! the difficulty of carrying that principle out fully, with anything more than a very few leading lines. The difference of the differences of a diffraction or wave-

length scale, between one part of the spectrum and another, as compared with an average refraction or prism representation, viz., some sixteen times, was found to defy all accuracy by any ordinary pen or pencil, and to mislead or confound the eye, as to the mere physiognomy of groupings of the lines. Then, worse still, nature herself, and spectrum-forming nature too, was being fought against, in having scales increasing their numbers for dispersion one way, when the prismatic deviations which produced these dispersions were going the other way. So at last it was determined that whatever the scale a pure theorist may eventually prefer to put a few spectrum places in at last, for his own purposes, the spectrum observer, in order to observe well, quickly, and safely throughout the whole spectrum must have :—

1. A scale according to nature, as to the direction of increase of its numbers.

2. Increasing therefore these numbers from red to violet, both because the prismatic deviations do the same, and because, when the temperature of bodies is gradually raised, from that of the air in which we live up to such point that they begin to be luminous, the first light given off is red ; and they only attain to violet light in the latest and most extreme degrees of heat eventually obtained.

3. Red therefore being the natural beginning of the spectrum, and all spectral numbers arranged as above, increasing towards the rest of the spectrum, the said red end requires to be placed on the left hand, so that every spectrum map may be told off as all writing and printing is made to read in all European countries, viz. from left to right, never from right to left.

4. Seeing that prisms will always be employed by some observers of the solar spectrum, and gratings by others, the scale to be used should be one whose general form, in equal parts, should divide the immense difference of physiognomy which exists between the spectra offered by these two instrumental methods ; that is, not compressing the red end so much as the prism does, nor compressing the violet so much as the grating does ; and this end is obtained most neatly, on an equally absolute foundation with wave-lengths, and in a handy set of whole figures by adopting the number of such waves to the inch, British.

The above points having been all fairly arrived at, after great sacrifices of both time and labour in the other direction, the Edinburgh experimenter proceeded without any further compunction to alter his spectroscope once more, and make it conform in all respects thereto, *i.e.*, to show the red end of spectra towards the left, and to increase spectral readings from left to right ; while he further applied new scales to his collection of spectrum maps in terms of wave-numbers. And then came the reward ; for not only did the same eye and pencil succeed in applying a wave-number scale more accurately than a wave-length one to prism-observed spectra, and make the correspondences between prism and grating spectra more numerous, perfect, and easily apprehensible, but the wave-number scale was found more suited naturally to the absolute requirements of the solar spectrum in itself. Or thus, while the wave-length scale, as represented in Ångström's grand normal solar, but diffraction spectrum stretches out the red end to such a degree that the lines there are so few and far between as to waste the very paper on which they are drawn, the wave-number method gently compresses them, or brings them twice as close together ; while again, if at the violet end the lines are so numerous, and closed packed in Ångström's map that they have hardly standing room, and can scarcely be separated one from the other—the wave-number method gives them twice as much space there, in a map measuring, on the whole, from red to violet, only the same length as Ångström's.

But there was a still higher reward to the experimenter, who, adopting the scale of wave-number, and finding he had more room for the violet end of the spectrum, began to pay more attention thereto ; for he then found that, crowded as were the violet lines in Ångström's diffraction map, they were not half crowded enough ; or rather that there were really in that part of the solar spectrum three or four times as many more lines still ; far more indeed than could have been inserted on the engraved plates of the Swedish philosopher, and many more than his diffraction grating was probably able to show. While therefore all strong lines throughout Ångström's map are believed to have been most admirably measured, and the far more numerous thin lines are also most truthfully rendered in the earlier and middle parts of the spectrum—the violet termination, what with the imperfect showings of his grating, and the contracted space of the wave-length scale map, has not been done justice to.

Yet this is a very material point in the physics of the sun ; for according to the preponderance of violet, over red, light, so may be assumed the intensity of the temperature of that light's origin. Whereabouts then did the increased number of lines in the violet observed by the Edinburgh experimenter with his prisms, over Ångström with his grating, place the photosphere of the sun as to temperature ?

This point, described by the experimenter in the *Transactions* of the Royal Society, Edinburgh, vol. xxix., for 1879, was approximated to by him in this manner :— Having collected from various sources several thousands of spectrum place observations, he reduced them all to wave-number scale, and then arranged them according to the temperatures of their sources of origin, or, as Mr. Norman Lockyer has since then termed it, their respective "heat-levels," and the following series was obtained :—

Source of origin of spectral light, when at freezing point as in telluric absorption spectra, has its maximum of lines at W.-N. place	= 39,000
Chamber absorption spectra at temp. 68° F. at ...	41,000
Flame lines at lamp-flame temperatures at	47,000
Gas-vacuum tubes illuminated by 1 inch induction spark	49,000
Chemical lines in 2 inch sparks	49,000
Chemical lines in 6 to 10 inch sparks intensified ...	51,000
And Ångström's diffraction solar spectrum	55,000

But the solar spectrum, as observed on this occasion in Portugal, showed its maximum of lines at 61,000 of the same scale ; or indicated that the temperature of the solar photosphere may be as much above the highest temperature yet attained by man, even with assistance of electricity in its condensed form, as that is above the freezing temperature of the upper strata of the earth's atmosphere.

Lastly, *Gaseous Spectra.*—Under this term are included both flames, especially blow-pipe flames, in the open air ; and electric illuminations inside so-called gas-vacuum tubes, such as those of Geissler and Plucker combined. But in all these cases the experimenter, finding that faintness of the light was the crying evil, changed the usual *transverse* method of looking at lines, or cones, of light, for an *end-on* view of the same.

Trying this first for the blow-pipe, whose flame of coal-gas urged by a stream of air could then, by a collimating objective applied to the anterior telescope, be safely looked into, though directed right towards the slit—the increased number of lines, their steadiness and definiteness in all the several hydro-carbon bands—and then the resolving of the mere haze in the field of view into closely ranked little lines or linelets, proved an inimitable reward, as well as a priceless source of the best kind of reference-data in all his subsequent inquiries ; especially too because these advanced results were procured without increasing either the temperature, or size, or combustion material of the flame at all.

Next applying the same principle to the Geissler-Plucker tubes, by having their form modified by M.

Salleron, so that they could be similarly looked at in the direction of the long line of the capillary—the effects were found almost startling in the brilliancy of the principal lines (chiefly indeed at the red end of the spectrum, for only weak sparks were employed) and in the immense number of additional lines in almost every tube-spectrum examined. These results had been communicated to the Royal Scottish Society of Arts in 1879, before it was ascertained that similar tubes for end-on use in photographing the violet lines had been made by the eminent Dr. van Monckhoven, at Gand, Belgium, three years earlier. But while fully acknowledging the Doctor's undoubted priority of invention, and inviting him to communicate his first published results at one of their meetings, the Society found the case already before them a perfectly independent invention; a part, too, of a more general system, and accompanied by a series of measures of some of the gas spectra, both in blowpipe flames and spark-illumined tubes, to a greater refinement than had ever been made before. They therefore graciously crowned the paper with a prize and printed it at full length in their *Transactions* for March, 1879.

Now some of these increased refinements in knowledge of the spectra of the gases referred to matters long in dispute before the world; and especially to the contention of whether the so-called "carbon-lines" of some observers seen by them in candle-flames, could possibly be the lines of that most refractory element carbon, or were not rather the lines of some of the very easily volatilised compounds of carbon, unless all the usual chemistry of carbon be utterly at fault. Herein the powers of the aurora spectroscope with its bright images, its still brighter end-on methods of viewing gas-flames, and its easy powers of rotation from one source of light to another, proved of inestimable advantage; for not only could large dispersions, approaching those employed on the sun, be used with effect, but the minutest line in one spectrum could be so quickly compared with a similar line in any other, and decided on absolutely as to whether it was or was not in the same spectrum place.

Wherefore the Edinburgh experimenter proceeded in the following manner: after repeating Prof. Swan's ancient observations and finding with him that all the various hydrocarbons gave more or less completely the same spectrum as the blue base of a candle-flame does, he set up for permanent reference, end-on, a blowpipe flame of coal-gas with common air as the best example of that kind of spectrum, viz., the spectrum of a something which vapourises at merely lamp-flame temperature. That that thing could be pure carbon, the chemists one and all declare is impossible, because no furnace heat can vapourise that element; but the Royal Society, London, had printed a paper declaring that the unknown agent must be carbon, pure and elemental, because the author of that paper had seen the same spectrum, not only in all combinations of hydrogen with carbon, but in those of oxygen, and also nitrogen, with carbon. This statement too was further strengthened by a Report from the Greenwich Observatory in 1877, to the effect that gas-vacuum tubes electrically illuminated, having been examined there spectroscopically, no sensible or material differences were found between carbo-hydrogens, carbo-oxygens, and carbo-nitrogens; the one common spectrum seen there must also, it was argued, though very different from the blowpipe flame spectrum, be the spectrum of pure carbon.

But as soon as the Edinburgh experimenter tried his end-on vacuum tubes he found an immense difference between carbo-hydrogens on one side, and both carbo-oxygens and carbo-nitrogens on the other; for the former, though with some other features constant, invariably showed many most brilliant lines in the orange, the citron, the green, and the blue; while the other tubes either had not any trace at all of those lines, or only so faint a marking as to indicate they were there as impurities and not as the whole contents of the so-called "vacuum-tube."

What were these lines then, so peculiar to carbo-hydrogen tubes? A reference to the coal-gas blowpipe flame showed that they were *its* characteristic lines; the lines, too, of an easily dissociable compound gas therein, and not of an ultimate and most refractory element; for as soon as the electric sparks illuminating the tubes were somewhat increased in intensity, quantity, and heat, these blowpipe, or we may now safely call them carbo-hydrogen, lines faded out of view; while the two elements which had made them, viz., pure hydrogen, showed its lines, and pure carbon showed, not its ultimate, elemental lines (which nothing short of the most powerful sparks, large batteries, and enormous condensers far above the private means of the Edinburgh experimenter can bring forth), but its low-temperature, compound-linelet, or *band*, spectrum.

Next, on examining the tubes of carbo-oxygen and carbo-nitrogen certain differences between them were detected, due apparently to the compound gas in each case being partly dissociated, and partly left untouched, by the simple, small induction-sparks employed. When largely dissociated, then carbon bands and oxygen lines were grandly present in one case, and carbon bands and nitrogen bands in the other; with some indications also of the compound's presence in either case, though never to the magnificent degree of the carbo-hydrogen in tubes of that gas. This, however, was merely for the simple reason that carbo-hydrogen is by nature a more magnificent "lighter-up" in luminous spectra; just as it is indeed the basis of all the means yet adopted in the history of mankind to correct the darkness of night; and there seems little chance that science will ever find anything better for every kind of occasion wherein we now employ candles, gas-lights, and lamps.

On further examining the carbon bands in the end-on tubes by a dispersion power of 33° from A to H, a peculiar structure was discovered by the experimenter in their component lines; and when he found that to be as distinct in a cyanogen tube which contained no trace of either oxygen, or more unusual still, hydrogen impurity, he considered it a proof that that electric spark-raised carbon-band (to which the chemists will probably not object) was the low-temperature spectrum of that element, and not the spectrum, as argued by M. Thalèn, of an oxide of carbon.

Many important points, therefore, seem to be indicated by these experiments, but with the general effect also of showing that spectroscopy loses much of its exceeding accuracy in power of discrimination, unless its observation be accompanied by some record of the particular "heat-level" at which the materials examined by it were rendered incandescent.

Hence a paper on these subjects was communicated to the *Philosophical Magazine*, London, in August, 1879; and further observations are now being carried on by the same experimenter on a new variety of his end-on tubes, prepared also by M. Salleron, and giving still brighter spectra than before, with the same electric illumination.

But all this is only while waiting for the aurora to appear, that phenomenon being the proper cynosure of this particular Edinburgh spectroscope. And now all men trust that the said aurora is soon to reappear, as the multifarious solar activities of a new sun-spot cycle have so evidently begun in the increased size and number of these spots ever since October, 1879; when they were critically considered, and openly announced in NATURE, to have at last shaken off the languor of their long minimum epoch, and to have begun in earnest their preparation for the new series now fairly under way.

(Since the above paper was written, the first of the new cycle of auroras to come, *has* been caught. See NATURE, vol. xxi. p. 492).

PNEUMATIC CLOCKS

To distribute the time with accuracy and uniformity in a large city is a problem of great utility and extreme importance. This problem has been all but completely solved by the pneumatic clocks erected since March last in the principal streets of Paris and among a considerable number of subscribers, who, for a halfpenny a day, receive the time from the observatory *every minute* without winding up or any care on their part. The details of the system established in Paris we take from an article by M. E. Hospitalier in a recent number of *La Nature*. The system consists of (1) a central station where the compressed air is produced and sent every minute through the system of tubes; (2) a distributing system of tubes with ramifications to streets and houses; (3) a series of

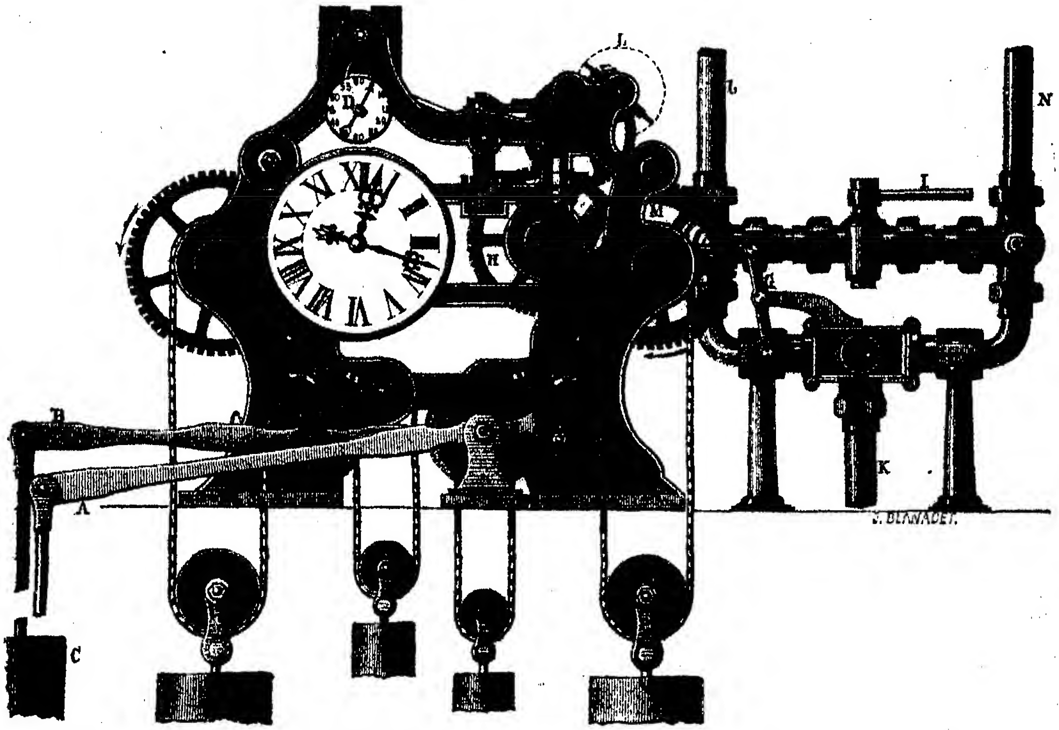


Fig. 1.—Distributing Clock of Compressed Air.

dials with pneumatic receivers established in the public streets and in private buildings.

At the central works a steam-engine sets in motion two pumps, which compress air into a large reservoir of about eight cubic metres, at a pressure of five atmospheres. This compressed air, by means of a special regulator, is transmitted to a second chamber called the distributing reservoir, where the pressure is kept at seven-tenths of an atmosphere by means of a simple automatic apparatus. This reservoir is put into communication every minute with the main distributing pipes for twenty seconds by means of a distributing clock shown in Fig. 1. The distributing clock comprises two quite distinct movements: the left movement is intended to set the clock going in the ordinary manner; the right movement is specially intended to work the distributing valve R. The seconds-hand is at D. At the beginning of each minute the air of the distributing reservoir arriving by the tube J in the distributing box is sent into the main distributing pipes by the tube M. At the end of twenty seconds a displacement of the lever G places the valve R in its second position. The tube N then communicates with the tube K, open to the atmosphere, while the tube J no longer communicates either with K or with N. The valve R remains 40 seconds in this position, to complete the minute, when a new displacement of the valve again places J in connection with N, and so on. All these displacements of the valve are effected by means of gearings arranged in the works of the distributing clock. The compressed air of the main pipes is utilised to wind up automatically the two movements by means of the levers A and B, which are connected with pistons placed in the cylinders C, and

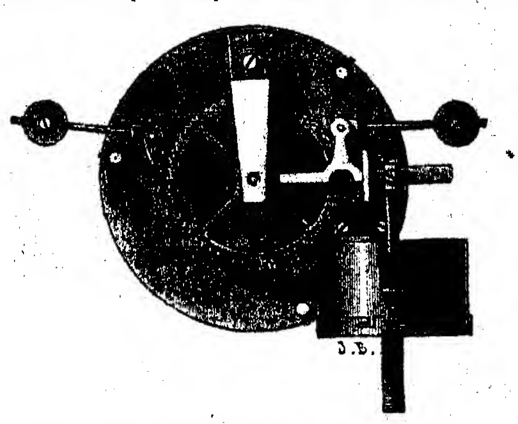

Fig. 2.—Dial Mechanism of Street and Private Clocks.

raised every minute by the compressed air to a distance exactly equal to that through which the motor weight has descended during the preceding minute. There is no need, therefore, to trouble about the winding up of the

distributing clock. This clock is regulated by the Observatory, by hand; but soon a special system will be established, by which the exact time will be distributed from the Observatory by electricity. As the system is established in duplicate at the central works, should anything go wrong with one clock the other is put in working order in a few seconds. The function of the distributing clock may be performed by the hand by working properly, every minute, the three-way tap, I, which plays exactly the part of the valve R.

For the system of distribution the air is sent every minute into the tube N, which bifurcates into a certain number of smaller branches, forming so many networks completely separate and independent, so that a derangement of one of the systems does not affect the others. The principal tubes, carried underground, are of wrought iron, and have

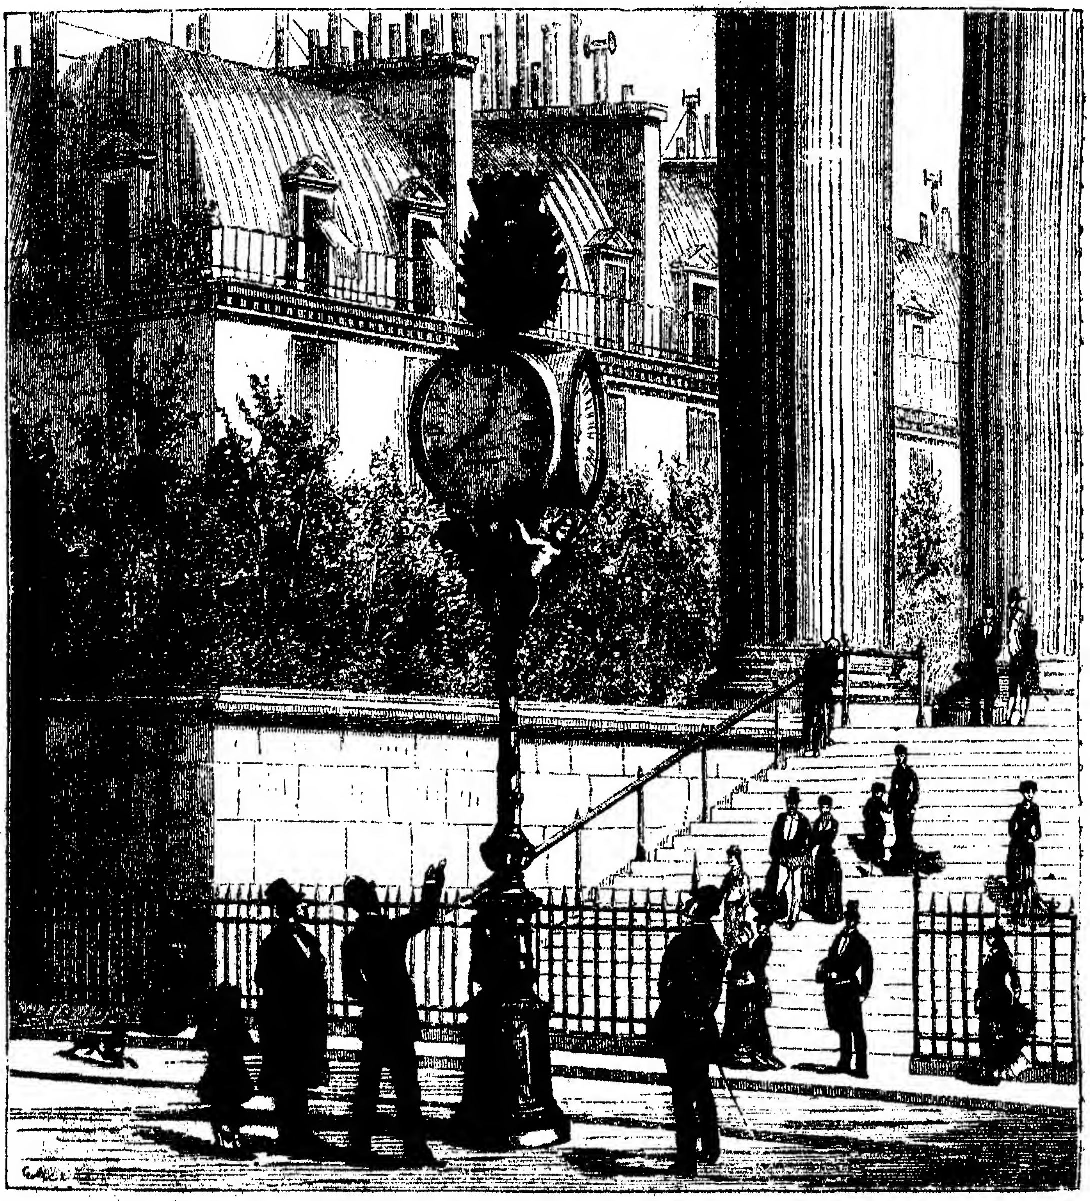

FIG. 3.—The Pneumatic Clock on the Place de la Madeleine.

an internal diameter of 27 millimetres. The tubes placed in private houses are of lead, 15 mm. in diameter; in apartments and passages this diameter is reduced to 6 mm., and the tube attached to the clock, in lead or india-rubber covered with silk, is only 3 mm. in diameter. With a pressure of seven-tenths of an atmosphere, by leaving the distributing system for 20 seconds in communication with the distributing reservoir, as we have said, it is easy to set the clocks going several miles from the central works, notwithstanding the inevitable escape from the pipes. Differences have occasionally been observed between some of the clocks, probably in most cases the results of mischievous meddling; these, and other accidents, however, become fewer and fewer, and will no doubt gradually disappear. Owing to the division of the service into various distinct networks, any flaw is soon detected and easily repaired.

Whatever be the form or size of the dial, public or

private, the mechanism is always the same. A caoutchouc bellows, like that used in Walker's pneumatic air-bells, is in communication with the main pipes. Every minute the pressure of the air raises it (Fig. 2); this bellows acts on a lever which draws a wheel of sixty teeth, in the axis of which is fixed the minute-hand. The wheel makes one-sixtieth of a revolution; a ratchet-click, shown on the left of the toothed wheel, prevents any return of the wheel. The movement of the hour-hand is effected by means of a small train of wheels, which is not represented in the figures. This small and very simple mechanism may be placed with the greatest facility in the interior of existing clocks, without changing the external form, substituting it for the old movement.

By means of a second bellows, the function of which is to wind up the bell of a pneumatic clock on a slightly different system, we may establish striking clocks. The price of the former to subscribers is 5 centimes a day, the striking clocks costing 6 centimes.

In Fig. 3 is represented the pneumatic clock of the Place de la Madeleine, furnished with its three dials, the movement of each of which is independent. The letters are clear on a blue ground. At night a jet of gas lights the interior, and the hour is clearly discernible at a considerable distance.

NOTES

WE have much pleasure in stating that Her Majesty has been graciously pleased to grant to the widow of John Allan Broun a pension of 75*l.* per annum. In NATURE, vol. xxi. p. 112, will be seen a full account of the life and works of that distinguished magnetician and meteorologist, whose life may truly be said to have been sacrificed through his devotion to the cause of scientific research.

THE following grants have been made from the Research Fund of the Chemical Society:—10*l.* to Mr. Kingzett for experiments on the atmospheric oxidation of phosphorus; 25*l.* to Mr. Watson Smith for the investigation of the di-napthyls and phenyl napthalene; 25*l.* to Messrs. Bailey and Munro for investigations of the colour reactions of certain metals and metallic solutions.

MR. AUBERON HERBERT is anxious to preserve our ancient monuments, but thinks the method proposed in Sir John Lubbock's Bill all wrong and unnecessarily harassing; indeed in his letter in Tuesday's *Daily News* he scents communism in Sir John's enterprise. He deprecates Government interference at all, and thinks the only effectual and enlightened method to be the education of the people into an intelligent respect for all our ancient monuments, a respect which would be a sufficient guarantee for their protection. Might not Mr. Herbert get Lord Norton to compile a series of reading-lessons on archæology after his lordship has completed the botanical reading-book to which we referred last week? These lessons might take practical effect in the course of a generation or two, by which time probably there would be no ancient monuments for popular protection. The obtuseness of Mr. Herbert's letter is almost phenomenal.

UNIVERSITY COLLEGE, London, is anxious to complete its buildings, and in connection with this purpose a meeting was held at the Mansion House last Friday. We have frequently had occasion to speak of the great services rendered by the institution to the raising and broadening of education in this country. It has not only itself aimed to carry out a high standard of education, but has given a strong and healthy impulse to older institutions, and led, directly or indirectly, to the establishment of other institutions in which science has its fair place. Of the desirability of completing the buildings of University College there can be little doubt. The sum required is large—105,000*l.*; but if Edinburgh could raise 90,000*l.* for a similar purpose surely the wealthiest city of the wealthiest country in the world need have little difficulty in raising the sum required. Of this sum 20,000*l.* has already been subscribed; about the balance we trust there will be no difficulty.

IN connection with the recent meeting to raise funds for the completion of University College buildings, Prof. Ray Lankester writes to yesterday's *Times*, animadverting in strong terms on the scandalous misappropriation of the funds left by Sir Thomas Gresham "for the purpose of providing a college which should rival the Universities of Oxford and Cambridge in the completeness of its appointments and bring the highest education to the very doors of the citizens of London." Prof. Lankester suggests that the present representatives of the Corporation, who appear so anxious to promote the educational interests of the metropolis, should restore "to University education in London a fair portion of the sum which the Corporation of London, in days long past, diverted to its own benefit from Sir Thomas Gresham's trust." But could not the Gresham funds be included in the inquiry of the Commission now being appointed by Government to investigate the whole question of the City Corporations? If not, it ought to be.

TWO important accessions have recently been received by the Herbarium of the Royal Gardens, Kew. The corporation of Carlisle has transferred to it the herbarium of Dr. Goodenough, who was formerly Bishop of the Diocese, and who died in 1827. This is rich in specimens of plants cultivated at Kew and Chelsea in the end of the last century, but which have hitherto been very imperfectly represented in the Kew Herbarium. The very extensive collections of mosses accumulated by the late Prof. Schimper of Strassburg, and upon which his well-known works upon this group of plants were based, has been purchased (together with the accompanying drawings and notes) from Prof. Schimper's family by the Baroness Burdett-Coutts, and also presented to Kew.

DR. M. C. COOKE having been placed by the India Office at the disposal of the authorities of the Royal Gardens, Kew, has now entered upon his duties as cryptogamist attached to the Herbarium, and will for the present take charge of the collections of non-vascular cryptogams.

MR. H. A. ROLFE, lately a gardener in the employ of the Royal Gardens, Kew, has been appointed by the Civil Service Commissioners, after a competitive examination, to the vacant post of second assistant in the Herbarium of the same establishment.

DR. WOODWARD has been appointed keeper of the geological department of the British Museum in succession to Mr. Waterhouse, who resigned about three months ago. Dr. Woodward has occupied the position of assistant-keeper in the department for many years, and is the editor of the *Geological Magazine*, in which, as well as in the *Journal* of the Geological Society, he has published numerous memoirs.

MANY lessons will, and already have been, drawn from the unprecedented explosion of gas in London on Monday; the results were disastrous enough, but we may congratulate ourselves that they were no worse. The science of the explosion is simple enough, as the daily papers have been telling the public; and when science is properly taught in our elementary schools such accidents can only be due to perversity, not lack of knowledge. We recommend this explosion and its immediate cause, to the consideration of Lord Norton.

OUR readers may remember that some months ago Sir William Thomson made several valuable suggestions as to the readjust-

ment of our present system of lighting our coasts, which, he maintained, is a fruitful source of danger to navigation. A Parliamentary paper has just been issued containing a correspondence between Lloyd's Committee and the Trinity House on these suggestions. Naturally the Elder Brethren of the Trinity House attempt to show that their system is by no means so unsatisfactory as Sir William Thomson maintains it is, though they admit it is by no means perfect. They assured Lloyd's Committee of two things—(1) that the lighthouse system was not in the crude state which Sir William Thomson appeared to imply, and (2) that its present custodians were actuated by a very earnest desire yet further to simplify and improve it. The Committee of Lloyd's remarked, in their reply, dated January 16, 1880, that they were glad to find that they were at one with the Elder Brethren in thinking that some distinctions more marked than those already existing would be useful. They had no special interest in Sir William Thomson's plan, but they had always understood that his inventions and improvements in electrical apparatus, the mariner's compass, and the sounding machine had been of great service to the community at large. We suspect there is much more in Sir William Thomson's animadversions and suggestions, the result of the practical experience of an eminent man of science, than the Elder Brethren of the Trinity House are willing to admit.

The engineers of the St. Gothard Tunnel are stated to be in a fair way to overcome the difficulty arising from the falling in of the roof in the part known as the "windy stretch." This stretch, which is 200 metres long, and situated almost directly under the plain of Andermatt, passes through strata composed alternately of gypsum and aluminous and calcareous schists, which absorb moisture like a sponge and swell on exposure to the atmosphere. It has given the contractors immense trouble, and has fallen in so often that it was seriously proposed a short time ago to allow it to collapse, and make a bend so as to avoid the "windy stretch" altogether. The expedient now adopted, which has so far been successful, is the rebuilding of the supporting masonry in rings of solid granite. The rings are each four metres long, so that in the event of any one of them giving way the others will not thereby be affected. The building is constructed slowly and with the utmost care; no imperfect stones are allowed to be used; the masonry is perfect, and the walls of extraordinary thickness—in the parts most exposed to pressure not less than ten feet. At the beginning of June only 34 metres of the "windy stretch" required to be revaulted.

M. Tresca, whose name has been connected with the Conservatoire des Arts et Métiers for about twenty-five years, no longer belongs to that establishment. His office has been suppressed by a recent decision of M. Tisard, the Minister of Agriculture and Commerce. This unexpected resolution has created some sensation in the Paris scientific world.

We have received the first volume of the *Archives* of the *Deutsche Seewarte*, a neatly-printed quarto volume of above 300 pages, with numerous plates, containing an account of the first four years' working of the Meteorological Office at Hamburg, 1875–78, under the able guidance of Dr. G. Neumayer, well known as the former Superintendent of the Flagstaff Observatory at Melbourne. The volume contains some elaborate reports, among which may be specially mentioned an account of the activity of the Office in the departments (1) of Marine Meteorology, (2) of Weather Telegraphy and Storm Warnings, (3) a Report on the Testing of Chronometers, and (4) a paper on the Non-periodical Monthly Variations of the Barometer. Subsequent annual volumes are promised in regular succession, and we look forward with confidence that an addition of much useful knowledge on the subject of meteorology generally will be gained by their publication. The *Seewarte* already possesses a library of 9,400 volumes, and includes that formerly belonging to Prof. Dove of Berlin, which was acquired at a cost of 1,500*l*.

A curious work, impressively illustrative of the "science" of the Dark Ages, has just been published at Berlin, under the title of "Compendium der Naturwissenschaften an der Schule zu Fulda in IX. Jahrhundert." Its purpose is to expound the works of Rhaban, the celebrated Abbé of Fulda (788-856). The Abbé, under the title of *De Universo*, published what would now probably be classed as an encyclopædia, and as we have said, its divisions and contents are a curious illustration of the state of systematic knowledge at the time it was written. Book I. treats of the Trinity and Angels; Book II. Patriarchs and Prophets; Book III. Men and Women spoken of in the Old Testament; Book VI. Man and the various parts of the Human Body; Book IX. the World, Atoms, Elements, the Sky, Stars, Meteors; Book X. the Almanack and Feasts; Book XII. the Earth; Book XIII. the Vertical (?) Parts of the Earth; Book XV. Philosophers, Poets, Sorcerers, Idols, Pagans; Book XVIII. Measures, Weights, Numbers, Music, Medicine, and Diseases; Book XX. War, Horses and Ships, &c. Of course the book is full of curious mythological and other mysteries, a remarkable feature, however, being the important part given to etymology; indeed it would almost seem as if all science consisted in good etymology.

Dr. R. F. Hutchinson of Mussooree, India, writes that on the afternoon of May 25 a hail-storm, remarkable for its fury, extensive area, and size and structure of its stones, enveloped that station, and Deyrab and Rajpore, at the foot of the hill. A discharge of stones as large as pigeon-eggs opened the attack, and this was followed by a continuous downpour of stones, oblate spheres as large as small marbles. The whole station was penetrated by these, and it presented the appearance of being strewn broadcast with acidulated drops. These stones were of pure, clear ice, and, barring their shape, quite amorphous. Not so the large stones, whose structure and mode of formation were very puzzling. First, an opaque nucleolus surrounded by a concentric nucleus of clear ice, and this by a radiating periphery. The nucleolus being opaque, was rapidly frozen; it must then have moved through alternate layers of hot and cold air to have received the concentric accretions of clear ice. The radiating periphery (which was translucent, but not transparent) quite puzzles our correspondent.

A valuable paper of observations of the aspect of Mars during his recent opposition, of the red spot of Jupiter, and the spots of Venus, by M. Terby, appears in the Belgian Academy's *Bulletin* (No. 3). The most delicate part of the work is that relating to the spots of Venus, of which he supplies ten carefully executed drawings.

Captain Douglas Galton gives an address to-day in connection with the Sanitary Institute at the Royal Institution.

The 126th annual meeting of the Society of Arts was held on the 30th ult., when the Report was presented and officers elected. The Society is in a more satisfactory condition than at any previous period.

Scientific Practice is the title of a periodical published three times a year for the students of the School of Practical Engineering at the Crystal Palace. No. 7, which we have received, contains several papers likely to interest young engineers.

Mr. W. Saville Kent's long-promised "Manual of the Infusoria" will be published by Mr. David Bogue. The complete MS. and drawings are in the printer's hands. The work will be issued in six monthly parts, the first of which is to be ready in October.

A NEW list of members of the Institution of Civil Engineers has just been issued, from which it appears that there are now on the books 1,217 members, 1,299 associate members, 579 associates, 18 honorary members, and 657 students—together 3,770 of all classes. At the same period last year the numbers of the several classes were 1,148, 1,200, 622, 17, and 591, making a total of 3,578, showing an increase at the rate of nearly 5½ per cent. During the past session the elections have comprised 2 honorary members, 43 members, 129 associate members, and 15 associates; and 160 students have been admitted.

A COMMISSION appointed on November 27, 1879, has visited the five French provincial observatories. A report has been written by M. Lœwy, sub-director of the Paris Observatory, discussed at a meeting of the directors of the establishment, approved by the Minister of Public Instruction, and published by the *Journal Officiel* on June 29.

IN a report which he has lately sent to the Foreign Office, the acting Consul-General at Bangkok remarks that the year 1879 will long be memorable in the provinces of Battambong and Chantaboon for the discovery of valuable sapphire mines in that part of Siam. Mines of inferior value have long been known in the neighbourhood, and about five years ago new mines were discovered by a native hunter. Being, however, in a very remote and secluded position, it was long before their fame spread to the Burman and Indian gem-traders and miners. Eventually they became more widely known, and large numbers flocked to them, especially from British Burmah. The largest sapphire hitherto found weighed, according to Mr. Newman, 370 carats in the rough, and when cut turned out 111 carats of the finest water. The ruby, onyx, and jade are also found in the district, but are apparently of inferior quality.

THE *Liverpool Courier* understands that the telephone has been successfully laid down from Childwall Church, Liverpool, to the house of a lady half a mile off who is unable to go out; the chants, hymns, and lessons are distinctly heard, but only fragmentary sentences of the sermon can be caught.

WE see from the *Otago Witness* of May 22 that Prof. Black of Otago University has commenced a second course of public lectures on chemistry, in continuation of the course last winter, to which we referred as having been attended by teachers from all parts of the province of Otago, many of them coming distances of sixty, seventy, eighty, and ninety miles. The present course promises to be quite as successful. The *Witness*, we are informed, publishes the lectures in response to several requests, and in view of the heartiness with which the course (both of last year and this) has been received.

MR. J. LEE JARDINE writes from Capel, Surrey:—"I felt what may have been the tremor of an earthquake on Sunday, June 27, at 9 p.m. I was sitting with friends talking and reading on the ground floor of a house close to a road, and noticed a low rumbling lasting two or three seconds; this was repeated five or six times in the course of four or five minutes, sounding so like the noise of wheels that I watched for a cart, but in vain. The last three or four times the rumbling was accompanied by a slight vibration sensible only to the feet. It was felt also by one of my friends, who remarked upon the curious sensation."

THERE was a severe shock of earthquake at Brieg, Switzerland, on Sunday. Many buildings were injured, but, so far as is known, no lives were lost. The movement was also much felt at Zermatt and Belalp, and very slightly at Geneva.

M. FERRY, French Minister of Public Instruction, presided at the first meeting of a commission established for the improvement of popular publications. It has been resolved that a sub-commission shall decide what works shall be rewarded and what subjects proposed by way of competition.

IN a work published by Dr. Ricoux of Philippeville, Algeria, on "Demographie figurée de l'Algérie," it is proved that marriages are more prolific than in France, the mean number of children being 3·67 in the colony, as contrasted with 3·07, in the mother country. In the first twenty years after the French occupation it was taken for granted that European children could not be reared in the colony. The increase of the European population is very remarkable; in 1830, 600; ten years afterwards, 27,000; twenty years, 125,000; thirty years, 200,000; forty years, 271,000. In 1880 the number is not yet known, but is probably 400,000, having been found 323,000 in 1876.

WE have received the Calendar of the "Tokio Daigaku," or University of Tokio for 1879-80. This university seems to be quite as complete in all its departments as any similar institution in this country, and the education provided seems, to judge from the examination papers, thorough. The place given to science is what it ought to be, on an equal footing with any other department in all respects. An interesting historical summary is prefixed of the introduction of Western learning into Japan.

THE *Report* of the Miners' Association of Cornwall and Devon for 1879 shows that the Association continues to do good work among the mining population of these two counties. The numbers attending the classes continue to increase, and the instruction given is well calculated to be of great service to a mining population. The *Report* contains a paper by Mr. A. T. Davies on the "Phenomena of the Heaves or Faults in the Mineral Veins of St. Agnes."

WE have received a very favourable *Report* (the 22nd) from the East Kent Natural History Society. The *Report* contains several good papers read at the meetings of the Society, the most important and the longest being that of Capt. McDakin, "An Outline and Index to the Geology of East Kent."

WE are asked to state by Mr. Walter Baily (not *Baillie*) that in our report of the Physical Society last week, p. 210, second column, line 29, *notes* should be *nodes*.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus erythræus*) from India, presented by Mr. Fred. Felix; a Banded Ichneumon (*Herpestes fasciatus*) from East Africa, presented by Mr. H. Hall; a Common Marmoset (*Hapale jacchus*) from Brazil, presented by Mr. T. Douglas Murray, F.Z.S.; a Java Sparrow (*Padda oryzivora*) from Java, a Spotted-sided Finch (*Amadina lathami*), a Chestnut-eared Finch (*Amadina castanotis*) from Australia, two Chestnut-bellied Finches (*Munia rubro-nigra*), a Yellow-bellied Liothrix (*Liothrix luteus*) from India, two Red-beaked Weaver Birds (*Quelea sanguinirostris*), a Crimson-crowned Weaver Bird (*Euplectes flammiceps*), a Paradise Whydah Bird (*Vidua paradisea*) from West Africa, a Brazilian Tanager (*Ramphocœlus brasilius*) from Brazil, a Bearded Tit (*Calamophilus biarmicus*), European, presented by Mr. St. Julien Arabin; two Common Peafowls (*Pavo cristata*) from India, presented by Miss Wedderburn; a Slender-billed Cockatoo (*Licmetis tenuirostris*) from South Australia, presented by Mr. H. F. Bussey; a Jaguar (*Felis onça*), two Huanacos (*Lama huanacos*), two Coypu Rats (*Myopotamus coypus*), two American Barn Owls (*Strix flammea*) from South America, deposited; a Cereopsis Goose (*Cereopsis novæ-hollandiæ*) from Australia, a Doubtful Toucan (*Ramphastos ambiguus*) from United States of Columbia, six Chinese Quails (*Coturnix chinensis*) from China, two American Kestrels (*Tinnunculus sparverius*) from America, an Ocellated Monitor (*Monitor ocellata*) from West Africa, purchased; a Red Deer (*Cervus elaphus*), a Reeves's Muntjac (*Cervulus reevesi*), born in the Gardens, three Upland Geese (*Bernicla magellanica*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

THE VARIABLE NEBULA NEAR ζ TAURI.—Though there has been no mention of late of observation of the vicinity of the nebula discovered near ζ Tauri on October 19, 1855, by Chacornac, at Paris, and of which he found not the least trace in November, 1862, it may be nevertheless hoped that attention has been directed to the neighbourhood, even if with negative results. As we do not find a sufficiently detailed account of Chacornac's experiences bearing upon this nebula in our astronomical treatises, we may recapitulate them here.

Chacornac tells us that when constructing, at Marseilles, the chart No. 17 of the Atlas employed in the search for small planets, he registered between December 3, 1853, and February 20, 1854, a great number of stars in this part of the heavens, and amongst others he observed, from January 26 to 31, a star of the eleventh magnitude, the position of which for the beginning of 1852 was in R.A. 5h. 28m. 35·6s., and Decl. + 21° 7′ 18″. At that time and later he did not perceive any nebulosity about it; at the Observatory of Paris on September 1 and December 17, 1854, with a refractor of ten inches aperture he did not detect any such appearance. On October 19, 1855, in verifying the chart of this region, he remarked a faint nebula about the star and delineated it upon the map. He was then, as he says, far from thinking that objects generally considered to be masses of small stars could vary in brightness like the isolated variables, and attributed the degree of visibility to the greater or less degree of transparency of our atmosphere. But under the idea that the nebulosity might really be a distant comet, he endeavoured to repeat his observation on following nights, though from clouds and moonlight it was not till November 10 that he could satisfy himself that the object was precisely as he saw it on October 19, having changed neither in position, extent, nor form. It brightness was particularly remarked on January 27, 1856, when it is recorded: "Elle offre l'apparence d'un nuage transparent qui semble reflecter la lumière de l'étoile ζ Taureau, et son aspect tout différent de celui de la nebuleuse 357 (Herschel II.) ne fait naître aucune idée de points stellaires visibles sur toute l'étendu de sa surface. Cette nebuleuse d'Herschel se présente en effet comme un amas d'étoiles qui s'aperçoivent distinctement séparées les unes des autres même avec un faible grossissement, tandis que le souvenir que je garde de la nebuleuse variable ne l'a fait comparer à un leger *cirro-stratus* strié de bandes paralleles: cette description est, du reste, en toute conforme au dessin de la carte."

From the end of January, 1856, until November, 1862, the dates of comparisons of this chart with the sky were not recorded, but on the 20th of the latter month Chacornac failed to see the least trace of the Nebula, though the star of the eleventh magnitude, upon which it was formerly projected, remained of precisely the same brightness. On frequent occasions subsequently, before notifying his discovery in April, 1863, he could see no vestige of nebulosity with the instruments at the Observatory of Paris. With regard to the appearance of the nebula Chacornac remarks: "Elle offrait une forme presque rectangulaire, dont le plus grand côté mesurait un arc de 3 minutes et demie, et le plus petit 2 minutes et demie." The eleventh magnitude, according to his position, precedes ζ Tauri, 12·6s., and is 4′ 26″ north of that star; it appears to be No. 907 of the zone + 21° in the *Durchmusterung*, where it is rated 9·4m., the scale of magnitudes in that catalogue not being identical with Chacornac's.

In the same neighbourhood is a variable star notified by Prof. Julius Schmidt, which follows the bright nebula *h* 357, about 23·8s., with 4′·2 less declination. It is No. 894, zone + 21° in the *Durchmusterung*, and there called 9·5m. According to Schmidt's observations it was 8·9 on February 4, 1861, 11·12 on March 21, 1862, 9 on January 9, 1864, and 10 at the end of the same year; he found its place for 1861·0 in R.A. 5h. 26m. 33·7s., and Decl. + 21° 50′ 47″; a twelfth magnitude follows it 3·7s., about 1′ 18″ to the south.

THE GREAT COMET OF 1880.—Dr. B. A. Gould has calculated a third parabolic orbit for the southern comet which he finds to represent his observations very closely; the elements are:—

Perihelion passage, 1880, January 27·41170 Washington M.T.

	°	′	″	
Longitude of perihelion ...	280	11	10	Mean equinox,
,, ascending node	7	7	38	1880·0
Inclination	35	12	27	
Log. of perihelion distance..	7·7268724			

Motion—retrograde.

He has also computed an ephemeris for February, from which we extract positions and distances for the period during which the tail was visible.

At Washington mean noon.

	Right Ascension. h. m. s.	Declination. ° ′	Log. distance from the Earth.	Sun.
Feb. 2	21 47 38	− 28 57·6	9·86856	9·53319
3	22 3 4	30 8·8	9·85728	
4	22 19 12	31 10·8	9·84799	9·62292
5	22 35 54	32 3·1	9·84064	
6	22 53 1	32 44·9	9·83521	9·69139
7	23 10 24	33 15·8	9·83167	
8	23 27 52	33 35·8	9·82994	9·74677
9	23 45 13	33 44·9	9·82997	
10	0 2 17	33 43·8	9·83165	9·79326
11	0 18 55	33 33·1	9·83487	
12	0 34 58	33 13·7	9·83949	9·83333
13	0 50 20	32 47·0	9·84538	
14	1 4 57	− 32 14·0	9·85237	9·86853

This gives the least distance of the comet from the earth 0·6757 of the earth's mean distance from the sun at about 6h. a.m. Greenwich time on February 9.

THE DIAMETER OF VESTA.—Prof. Tacchini has taken advantage of the recent favourable opposition of this planet to measure the apparent diameter, which with a power of 1,000 on his refractor he found to be, on June 9, 1″·706. This value reduced to the mean distance is about double that resulting from Secchi's observation at the opposition of 1855, when he judged the apparent diameter to be a little less than that of the first satellite of Jupiter, or about 0″·8, but "molto più debole di luce, e di colore ranciato carico." For distance *unity*, Tacchini's measure gives 1″·96, and Secchi's estimate 1″·01. Probably we may hear of other measures of Vesta at the opposition of the present year, made with large instruments.

GEOGRAPHICAL NOTES

THE collections in natural history and ethnography brought home from the coasts of Siberia and Eastern Asia by the *Vega* are to be exhibited in the old hall of the Royal Library at the Palace, Stockholm. The exhibition was opened yesterday, and Baron Nordenskjöld invites naturalists and geographers to visit the collection.

AT the German Athenæum last week the Chevalier Ernst von Hesse Wartegg gave a lecture on his recent travels in North Africa, comprising chiefly the southern parts of Algiers and Tunis and the rarely-visited frontier regions between these two countries. Herr von Wartegg's principal aim was the thorough revision and completion of the very defective Tunisian map of the French General Staff, edited in 1858, and the investigation of the Schott region in Southern Tunis, adjoining the Lesser Syrtes. The first object was, according to the lecturer, satisfactorily completed by the substantial aid of the Tunisian Government and the foreign consular body at Tunis. To point out a few instances of the deficiency of the French maps, Herr von Wartegg mentioned the large river Kassab, a tributary of the Medjerdah, which in the map empties into the Mediterranean about 200 kilometres from its actual mouth. Large lakes are entirely omitted, and cities invented which do not exist. The main fault of the map is the erroneous spelling of the topography, Frenchifying and mutilating nearly every name. For instance, the Arab word Sandjak has been turned into "Saint Jacques," &c. Regarding the well-known project of Capt. Roudaire and M. de Lesseps, the lecturer states that neither the geological formation nor any other sign indicates the former connection between the so-called "submarine basin" in Southern Tunis and Algiers, and he believes, contrary to the sanguine dreams of Capt. Roudaire, that it never was connected with the Mediterranean. According to his observations the submarine basin in the interior approaches the coast only at a distance of about seventy miles, and the canal to be constructed across the isthmus would have to be therefore of that length. The cost of such a work, rivalling the Suez Canal in magnitude, would never be in proportion to the benefit derived, which latter is entirely doubtful. No thorough investigation of the region was ever made, and its results would never be certain, as the constant vibration of the air in this hot climate and the deceptions caused by frequent *fata morganas* render scientific measurements very problematic. If

the connection between the two basins were to be established, some of the most flourishing cities of the Schott region, like Tooser and Nephta, would be submerged by the floods, and most probably all the large date-tree forests of the Djerid destroyed by the change of climate and the increased moisture. Herr von Hesse Wartegg spoke at length of his travels through the Regency, and mentioned some curious meteorological and botanical observations. The traveller brought back with him a large collection of plants, ethnological objects, and insects, as well as drawings and photographs. He will exhibit his collection at his lecture before the British Association at the forthcoming Swansea meeting.

THE new number of the Geographical Society's *Proceedings* opens with the presidential address on the progress of geography, in which the chief space is devoted to the Arctic regions and Africa; it is supplemented, however, by a summary of Admiralty and Indian surveying operations. A letter is next given from Mr. James Stewart of Livingstonia to the Free Church of Scotland, furnishing a further account of his recent explorations north-west of Lake Nyassa, up to the south end of Lake Tanganyika, and which was accompanied by valuable longitude observations. The latter is illustrated by Mr. Stewart's route surveys, which are of great value from a geographical point of view. Among the notes information is given respecting Dr. Lenz' progress in North-Western Africa, which had reached the Foreign Office through the British Minister at Tangier. Dr. Lenz is stated to have crossed the Atlas, and Moorish protection being refused him beyond Terodant, he has pushed on alone towards Timbuctoo and the Soudan, disguised as a Mohammedan doctor and accompanied by a Moor named Hadj Ali. There are also interesting particulars respecting the movements of a Roman Catholic missionary expedition to the Matabele country and the Upper Zambesi region.

SIGNOR FRACCAROLI, the delegate of a society formed last year at Milan for the development of commerce with Central Africa, has lately paid a visit, in company with Emiliani Bey, to the centre of the Darfur province, which he found in a state of desolation from the recent wars. After a vain attempt to reach the summit of Jebel Si, a lofty isolated peak in the Jebel Marra, he returned to Khartum, whence he expected to proceed on a journey up the Balor el Ghazal.

COUNT LOUIS PENNAZZI is about to undertake a journey in Abyssinia and the neighbouring region. He proposes to start from Massowah and visit the city of Gondar and Mount Debra Tabor, hoping to find King John and obtain from him an escort to accompany him through the Gojam province and to the Blue Nile. Thence he will proceed in a west-south-west direction, following the Sobat and the White Nile along the eighth parallel, and eventually join Signor Gessi.

NEW METALS

WITHIN a period of about two years the chemical world has been startled by the successive announcement of the discovery of no less than fourteen[1] new elementary bodies. All of them are classed as metals, and eleven are said to belong to the yttrium or to the closely-allied cerium group. Without pausing to examine the advisability of announcing the discovery of a new element whenever an unknown reaction crops up, we purpose to give a brief account of these discoveries, and to investigate, as far as possible, what claim they may have to be honoured with a place in our lists of the chemical elements.

In July, 1877, M. Sergius Kern published[2] the discovery of a new metal belonging to the platinum groups, to which he gave the name *davyum*. The davyum was, he said, contained in the latter portions of the platinum ores precipitated by hydrogen at 100° together with the rhodium and iridium. The metals having been heated with barium chloride and chlorine in the usual manner, the rhodium and iridium were fractionally precipitated by acid sodium sulphite, and the davyum contained in the filtrate thrown down with ammonium chloride and nitrate. From this double chloride an ingot of the metal weighing 0·27 gramme was obtained. The properties of this metal and its compounds, as stated by M. Kern, all agree more or less closely with those of the other platinum metals. It is difficultly fusible, dissolves only in *aqua regia*, possesses an atomic weight of about 100, &c.

[1] M. Lecoq de Boisbaudran's *gallium*, the existence of which has now been fully established, is not included in this number.
[2] *Chemical News*, vol. xxxvi. p. 4.

Its specific gravity is, however, said to be 9·38, which is lower than that of any other metal of this group, but approximates to a mixture of rhodium with a little iron. The characteristic reaction is stated to be the red colour produced by potassium sulphocyanate, but unfortunately both iron and ruthenium produce the same result, and M. Kern does not tell us what means he has adopted to get rid of traces of these and the other platinum metals, or to convince himself that they were absent. It is to be regretted that no protest, except a letter of Mr. W. H. Allen,[1] has been raised against this endeavour to foist a "new metal" upon the chemical world, and that too by a chemist who has signallised himself by such inaccurate results in other directions.

Turning now to the recent additions to the yttrium metals, we have in the first place to notice a contribution by Marignac. In the summer of 1878, after examining the earths from gadolinite to establish the existence of terbium, this chemist was induced to attempt a further separation of the erbia obtained in the course of his experiments. These investigations led to the discovery that this pink earth contained another white earth with a somewhat higher atomic weight, and whose salts gave no absorption-spectrum. To the metal contained in this earth the name *ytterbium*[2] was given. These results have recently been fully confirmed,[3] and we may accept the existence of this metal as an established fact. Marignac gave some of his specimens to his colleague, M. Soret, to examine spectroscopically. The latter chemist, operating with sunlight and with a spectroscope of high dispersive power, found that certain lines in their absorption-spectra did not agree with those of erbia, and that this was particularly the case with regard to the violet and ultra-violet portions of the spectra. From these results he was led to suspect the presence of two new earths, one of which he named provisionally X, leaving the other unnamed.[4] All attempts to separate either of these earths were, however, futile.

Shortly afterwards Lawrence Smith published[5] the results of some investigations on these earths obtained from the mineral samarskite, abundant in North Carolina and other American localities, instead of from gadolinite. As the result of his investigations he announced the discovery of a new earth, to which, however, he gave no name. It was, he said, a yellow earth possessing most of the properties of terbia, but differing from it in some reactions. Marignac, who received a sample of this earth, found,[6] on examining it, that its properties did not differ appreciably from those of terbia, and we may very well accept the verdict of this distinguished chemist. Lawrence Smith also stated that the earth called X by Soret had been discovered by him in samarskite about a year previously, and had been named *mosandrum*. He has since admitted[7] that the salts of this metal give no absorption-spectrum, and he has furnished us with no details as its special properties, mode of separation, &c., which are conclusive enough to admit of its immediate recognition as a new metal.

We now come to a number of "new" metals all belonging to the same group, and mainly distinguished by slight differences in the absorption-spectra of their salts and in their atomic weights. The earth named X by M. Soret, as well as the one he left unnamed, have been already referred to. Besides these, two new metals have been announced by M. Delafontaine,[8] which he has named *phillipium* and *decipium*. The former is a yellow earth with an equivalent between that of yttria and terbia, the latter a white earth with a higher equivalent; both possess indistinct absorption-spectra. M. Soret, who has examined the absorption-spectra very carefully, thinks it probable[9] that the mixture formerly known as erbia may contain phillipia or his unnamed earth, together with the earth X and the real erbia, besides other earths giving no absorption-spectra. Of decipium we have no confirmation. These earths have also been investigated by Cleve, in conjunction with Thalén. They came to the conclusion that there are three distinct earths which yield absorption spectra in the old erbia.[10] These they named *thulium*, *holmium*, and the real *erbium*. Subsequently they have admitted[11]

that M. Soret has priority in the discovery of these new earths, since the absorption-spectrum of holmium coincides exactly with that of the earth X., and thulium is probably the same as the unnamed earth of Soret or the phillipium of Delafontaine. The existence of these three earths in the yttria group is also acknowledged to some extent by Marignac;[1] it may therefore be considered tolerably certain that these new earths are really contained in this group, whatever names they may ultimately receive. In connection with this we must not omit to mention the investigations of M. Lecocq de Boisbaudran. He has confirmed[2] the results of MM. Soret and Cleve concerning the three earths mentioned above, and even thinks that he has obtained sufficient evidence of a fourth, named *samarium*. He admits, however, that its separation is too tedious to allow of its extraction in a state approaching purity.

In operating upon the mixture of earths formerly known as erbia Nilson was able to separate, besides the earths giving absorption-spectra and besides ytterbia, another white earth, whose salts gave no spectrum and which possessed a low atomic weight (about 45). The new metal contained in this earth he named *scandium*,[3] and he states that it is distinguished by a special spark-spectrum. These results have been confirmed by Cleve,[4] and he has remarked that many of the properties of this scandium agree closely with the metal whose existence was predicted by Mendelef under the name of *ekabor*.

The following are a few of the more striking of these resemblances:—

Ekabor	Scandium
At. wt. = 44	At. wt. = 45
Only oxide = Eb_2O_3	Only oxide = Sc_2O_3
The oxide is white, infusible, and nearly allied to yttria.	
S.G. of oxide = 3·5	S.G. of oxide = 3·8

On the other hand it is difficult to understand how a metal with such a low atomic weight could remain associated with others possessing atomic weights three or four times as great throughout the long process of fractional separation. According to all analogy with yttrium, terbium, and erbium, it ought to remain with the first of these. The following table of the metals of the yttrium group will illustrate the present state of our knowledge with regard to them. The atomic weights are calculated on the supposition that their oxides are of the general formula M_2O_3—those in italics give distinct absorption-spectra:—[5]

	Scandium (?)	Sc = 45	(Nilson)
	Yttrium ...	Y = 89	Bunsen and Cleve)
Probably identical	*Phillipium*	Pp = 111	(Delafontaine)
Probably identical	*Unnamed metal of Soret* ...		Undetermined
Probably identical	*Thulium*		Undetermined
Probably identical	*X. of Soret*		Undetermined
Probably identical	*Holmium*		Undetermined
	Terbium ...	Tr = 147	(Marignac)
Probably identical	*Samarium* (?)		Undetermined
Probably identical	*Decipium* (?)	Dp = 159	(Delafontaine)
Probably identical	*Yβ*	= 149·4	(Marignac)
	Yα	= 156·7	(Marignac)
	Erbium ...	Er	Undetermined
	Ytterbium ...	Yb = 172	(Marignac)

It must also be remarked that Delafontaine has suspected that the didymia obtained from cerite differs from that from samarskite, although Lecoq de Boisbaudran and L. Smith have since shown that the absorption-spectrum of the didymia salts may be considerably altered by making the solutions strongly acid, &c. And it is of course open to question whether some of the spectroscopic differences ascribed to different metals may not be due to differences in the concentration, acidity, &c., of the solutions employed.

It only remains to mention the newly-discovered metals—*norwegium* and *vesbium*. The former was announced to English chemists some twelve months ago by Dr. T. Dahll.[6] It is, he says, a white metal, allied to copper in many of its properties, but with a melting-point of about 350° C., and a specific gravity of about 9·4. Its atomic weight would lie between 141·6 and 150·6. The latter metal (vesbium) has been stated by M. A. Scacchi to be present in a green incrustation found on Vesuvius in the fissures of the eruption of 1631. It is, he says, present in the shape of a red metallic acid, giving colourless salts with the alkalies. Many of its properties agree with those of molybdenum or vanadium, particularly the latter, though M. Scacchi believes that both these metals are absent. Of numerical data only the proportion of silver in the silver salt is given. This is stated to be 48·8, while for the corresponding vanadium salt it would be 52·1, a coincidence too close to be disregarded.[1] Up to the present we are without any confirmation of the existence of these two metals, and we cannot do otherwise than suspend judgment on them for a time.

Indeed the scepticism which the chemist, in common with other scientific men, ought to practise cannot be too strongly insisted upon. No discovery of such importance as that of a new element should be generally accepted until it has been submitted to a series of rigorous confirmatory tests. It is obviously so much better to defer definite judgment until sufficient facts have been collected than to accept a hasty conclusion, probably based only upon one or two anomalous reactions. How often it happens that the chemist describes a reaction not as he saw it, but as he thought he saw it, or as he hoped to see it! Even in cases where the reaction possesses some peculiarity too little attention is often paid to the effects which even traces of other substances may produce, or to any extraordinary conditions under which the experiment may be made, and the chemist at once imagines that he has discovered a "new element." Time alone will prove how many of the fourteen substances enumerated above will pass the ordeal of further and perhaps more rigorous investigations.

T. S. Humpidge

Since writing the above M. Marignac has published an account of some investigations on the earths contained in samarskite.[2] He divides these earths into four groups, according to their solubility, in a saturated solution of potassium sulphate:—

(i.) Those earths soluble in less than 100 parts of the solution.
(ii.) Those soluble in 100 to 200 parts.
(iii.) Those only slightly soluble.
(iv.) Those insoluble.

Group (i.) contains only well-known earths, and particularly yttria and terbia. Their equivalent was always below 119 (oxide = MO). Group (ii.) consists of earths with an equivalent between 119 and 115. It contains traces of the preceding and following groups, but principally consists of a pale yellow earth with an equivalent of about 120·5, and without any absorption spectrum. This earth he provisionally calls Yα; its properties do not agree with those of any of the others of this group mentioned above. Group (iii.) contains a considerable quantity of terbia and didymia, together with a colourless earth yielding an absorption-spectrum agreeing with that of Delafontaine's decipia, or better with that of Lecoq de Boisbaudran's samaria. This earth he calls Yβ, and he is of opinion that decipia, samaria, and Yβ are practically one and the same earth. The equivalent he makes 115·6 (oxide = MO), which would give an atomic weight of 149·4 (oxide M_2O_3). Group (iv.) consists principally of didymia, together with considerable portions of the other earths, which it is almost impossible to completely separate.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

Oxford.—At Trinity College one Millard Scholarship, tenable for four years during residence, and of the annual value of 80*l*. without limit of age, will be awarded in October next for proficiency in natural science if any candidate of sufficient merit offers himself. The subjects of examination will be chemistry and physics. Candidates may also offer mathematics, if they wish to do so, and give notice a week before the examination. Special weight will be attached to excellence in one or two subjects, rather than to a less thorough knowledge of all. The scholar elected will not necessarily be required to commence residence immediately. The same papers will be set in chemistry and physics as in the examination for the Natural Science Scholarship at Exeter College. Every candidate will be considered as standing at both colleges, unless he makes a statement to the contrary on entering his name. Candidates are requested to state which college they would prefer in the event of their being elected at both colleges. The president will receive the names of candidates, and their testimonials of character, on Wednesday, October 13, between 8 and 9 p.m.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 17.—"Notes of Observations on Musical Beats." By A. J. Ellis, F.R.S.

This paper gave the results of three years of observations made for the purpose of discovering the cause and amount of error in Appunn's reed tonometers, and for obtaining materials for the writer's "History of Musical Pitch" (NATURE, vol. xxi. p. 550). The principal results were these:—In free air the number of beats between two musical notes are exactly equal to the difference of their pitch, or number of double vibrations made in one second by the lowest partial or prime; this was proved by the exact agreement of the pitch of the forks in Scheibler's tonometer, determined by such beats, with their measurement by Professors McLeod and Mayer, and with the results of Koenig when reduced to a uniform temperature. For this reduction the coefficient by which the number of vibrations must be multiplied for each degree Fahrenheit varies from ·00004 to ·00006, and may be assumed as ·00005 (forks flattening by heat and sharpening by cold). It differs for different forks, and depends on the action of temperature on elasticity. Tuning-forks are very stable, proved by the fact that Scheibler's extreme forks have not varied by one-tenth of a vibration in a second since his death in 1837, and that a fork measured and marked by himself as 438 single vibrations, that is, 219 double vibrations, fifty years ago, although much rusted, has not lost more than 0·3 d. vib. Beats which take place in confined compressed air, as in Appunn's reed tonometers, are accelerated by 76 in 10,000, or, say ¾ per cent., as a mean; proved by taking the beats within and without the box of the tonometer, and determining the pitch of the reeds by beats with Scheibler's forks, the two means agreeing precisely. All beats are beats of the simple partial tones of which the compound tones are made up; proved by the bell-like beats of the disturbed unisons and higher consonances in Appunn's tonometer, while the "surge" of the non-beating partials was distinctly evident, and by the beats of the higher upper partials themselves of very low and very compound reed tones in a single note. The independent existence of the partial tones, without any assistance from reinforcing resonance cavities, was proved by determining the pitch of low reeds by the beats of their upper partials with the prime or lowest partial of different forks; thus the pitch of a reed of 31·47 vib. was determined by beats with partials 7, 9, 10, 11, 12, 13, each with a different fork, and the results varied only from 5 to 9 in the second place of decimals; the pitch of a reed of 11·90 vib., of which the prime was quite inaudible, was determined by beats with partials 20 and 28, giving 11·88 and 11·91 respectively. The best mode of constructing a tuning-fork tonometer was shown to be dependent on the fact that all tuning-forks contained their own octave, or second partial, distinctly enough to count beats between it and a fork forming its approximate octave, so that there was no occasion to tune an octave. Practical directions were given for this construction. Practical directions for performing the experiments on Appunn's tonometers have been deposited at the South Kensington Museum, where the instruments used exist, especially for the delimitation of the higher considences and consonances where the terms of the ratios are any of the numbers 1 to 16.

"Preliminary Note on the Ossification of the Terminal Phalanges of the Digits," by E. A. Schäfer, F.R.S., and F. A. Dixey, B.A.

The diaphyses of the ungual phalanges of the digits offer an exception to the usual mode of ossification of diaphysial bones (including the other phalanges) in the fact that the calcification of the cartilage and its attendant changes begins at the tip and not in the centre of the diaphysis. The subperiosteal intramembranous ossification also commences at the same point—the tip, namely, of the cartilage—as a cap-like expansion over the end of the cartilage. The irruption of the osteoblastic subperiosteal tissue also first occurs here, so that this part seems to correspond morphologically with the centre of the shaft of other

long bones. The expanded portion of the phalanx which bears the nail, claw, or hoof is entirely formed by an outgrowth of the subperiosteal bone, and is not preceded by cartilage.

A detailed account of the mode of ossification of these phalanges will be shortly published.

"The Aluminium-Iodine Reaction," by J. H. Gladstone, Ph.D., F.R.S., and Alfred Tribe, F.C.S., Lecturer on Chemistry in Dulwich College.

"Note on the Discovery of a Freshwater Medusa of the Order Trachomedusæ," by E. Ray Lankester, F.R.S. (See NATURE, vol. xxii. p. 147.)

"Note on the Bearing on the Atomic Weight of Aluminium of the Fact that this Metal occludes Hydrogen," by J. W. Mallet, F.R.S.

Zoological Society, June 15.—Prof. W. H. Flower, F.R.S., president, in the chair.—The Secretary exhibited the skin of an antelope received from the Gaboon, and remarked that it appeared to belong to the female of an undescribed species of *Tragelaphus*, allied to *Tragelaphus spekii*, which he proposed to name *T. gratus*.—Dr. A. Günther exhibited and made remarks on a series of horns of the Sambur deer of Borneo.—Mr. W. T. Blanford made some remarks on the proper name of the Himalayan marmots, now living in the Society's Gardens, which he believed to be *Arctomys hodgsoni*.—Prof. Mivart called attention to the Medusæ, now living in the Victoria-Lily house, in the Botanic Gardens, Regent's Park.—Mr. Edward R. Alston read a paper on *Antechinomys* and its allies, in which he described the anatomy of that little-known marsupial. He regarded the four genera, *Phascologale*, *Antechinus*, *Podabrus*, and *Antechinomys* as constituting a sub-family of the *Dasyuridæ*, the first and the second, and the third and the fourth, being most nearly related to one another.—Mr. G. E. Dobson read a paper on some new or rare species of Chiroptera, in the collection of the Göttingen Museum. Amongst these was a new species of *Megaderma* from Australia, which, on account of its large size, Mr. Dobson proposed to name *Megaderma gigas*.—Mr. W. A. Forbes read a paper on the anatomy of *Leptosoma discolor*, and adduced further evidence to show that this bird is related not to *Cuculidæ*, but to the rollers (*Coraciidæ*).—A second paper by Mr. Forbes contained remarks on two rare Ploceine birds in the Society's collection (*Viaua splendens* and *Pytelia wieneri*).—Mr. Forbes likewise read some notes on the anatomy of a male Denham's Bustard, lately living in the Society's Gardens, and on its mode of "showing off" when alive.—Mr. Edgar A. Smith read the descriptions of twelve new species of shells from various localities. Specimens of all but two were in the collection of the British Museum.—Sir Walter Elliot, K.C.S.I., read some notes on the Indian Bustard, and its manner of "showing off," as observed by him in India.—Mr. F. H. Waterhouse read a list of the dates of publication of the several parts of Sir Andrew Smith's "Illustrations of the Zoology of South Africa."—Mr. A. W. E. O'Shaughnessy read the description of a new species of lizard of the genus *Anolis*, from Ecuador, which he proposed to call *Anolis buckleyi*, after its discoverer, Mr. Clarence Buckley.—Mr. Sclater read a paper containing a list of the certainly-known species of Anatidæ, with notes on such as have been introduced into the zoological gardens of Europe.—Mr. Wilfred Powell read some notes on the habits of the Mooroop (*Casuarius bennetti* of New Britain).

Anthropological Institute, June 22.—Edward B. Tylor, F.R.S., president, in the chair.—Mr Wilfred Powell exhibited a collection of ethnological objects from New Britain and New Ireland. Amongst them was a mask formed from a human skull and a sling which was chiefly remarkable for its great length.—Don Francisco P. Moreno exhibited two skulls from Patagonia (Rio Negro).—Prof. W. H. Flower, F.R.S., gave the substance of a paper on a collection of crania from the Fiji Islands. The two principal islands of this group are Viti Levu and Vanua Levu; until very recently we have had no skulls from either of these islands, all that have reached Europe having come from one or other of the small Eastern Islands. There has been for some time in the Museum of the Royal College of Surgeons one skull obtained from the hospital at Hobart Town, which was said to be Fijian, but this specimen is not at all typical, but rather misleading in its characters. These skulls (fourteen in number) were all found by the Baron Anatole von Hügel in the same cave in the Landongo district, quite the southern end of Viti Levu. No skull has ever been brought from the northern island, Vanua Levu. The most noticeable feature is the great similarity between the skulls; in every essential particular they are precisely alike, proving that they belong to a pure race. They are the longest and narrowest of any known, the average cephalic index being 66; they are also very high skulls. All these skulls are prognathous and platyrhine, the alveolar index being 102 and the nasal index 57. They are also mesosemes, having an orbital index of 85. A great difference is seen between these skulls and Samoan skulls, and five skulls from Vanua Velava, where the two races are brought into contact, show characters between these two extremes:—

	Bi	Hi	Ai	Ni	Oi
Fiji	66	74	102	57	85
Vanua Velava ...	72	75	101	50	88
Samoan	83	78	98	44	92

Meteorological Society, June 16.—Mr. G. J. Symons, F.R.S., president, in the chair.—T. W. Barry, M.D., A. W. Martin, and C. E. Peck, were elected Fellows, and Señor A. Aguilar and Dr. H. H. Hildebrandsson were elected honorary members of the Society.—The following papers were read:—Ozone in nature, its relations, sources, and influences, &c., from fifteen years' observations ashore and afloat under all condition, of climate, by J. Mulvany, M.D., R.N. The meteorological elements with which ozone is most intimately associated are such as occasion high vapour tension and a high degree of saturations therefore it is promoted by wind passing over a large aqueous expanse and by heat producing rapid evaporation. Hence heat if humid is no bar to atmospheric ozonisation, but no definite relation exists in the atmosphere between that *per se* and ozone; its relation to humidity is more definite and direct, but subject to many exceptions; in consequence of this relation it most abounds where its chemical qualities render it most useful. It appears to be formed in the upper strata and to be carried downwards by rain-drops, whose office is vehicular. The spherules of water which constitute clouds, and have their origin in radiation and condensation, have a similar office. Ozone does not appear to diffuse readily downwards, so that when the lower strata are robbed of ozone by jungle, &c., a considerable difference in the ozonic condition close to and at 170 feet above the surface may exist. The author is of opinion that no disease can be clearly traced to ozone as met with in the atmosphere.—The average height of the barometer in London, by Henry Storks Eaton, M.A., F.M.S.—Note on a waterspout observed at Morant Cays, Jamaica, March 23, 1880, by Lieut. Alfred Carpenter, R.N., F.M.S.—Account of a balloon ascent from Lewes in a whirlwind on March 23, 1880, by Capts. James Templer and H. Elsdale.—Results of meteorological observations made at Stanley, Falkland Islands, 1875-77, by William Marriott, F.M.S.—A new thermograph, by William David Bowkett.—The winter climate of Davos, by C. T. Williams, M.D., F.M.S. Among the high altitude sanitaria of Europe, Davos at present enjoys the greatest reputation, partly on account of its easy accessibility, and partly on account of certain peculiarities of position and shelter. The valley of Davos lies in the canton of the Grisons, between the valleys of the Lower Rhine and the Upper Engadine. The valley runs from N.N.W. to S.S.E. for about ten miles in length, with an average breadth of about a third of a mile, being for the most part of this extent a plain gently sloping towards the north, and varying in elevation from 5,400 to 4,500 feet. Davos Platz is 5,105 feet above the sea level. The author discusses the observations made during the four winters of 1876-7 to 1879-80. The peculiar effects of Davos winter climate seem to depend on (1) the rarefaction of the atmosphere; (2) its dryness; (3) the absence of strong currents, owing partly to shelter and partly to the uniform layer of snow spread around; and (4) the large percentage of the *direct* solar rays reaching the locality, owing to rarefaction of the air, and also the considerable amount of heat reflected from the extensive snow plain in front of the village of Davos Platz.

Royal Microscopical Society, June 9.—Dr. Braithwaite, vice-president, in the chair.—The following papers were read:—On the relative visibility of minute structures in solutions of phosphorus, sulphur, &c., by Mr. Stephenson.—On the life-history of the Diatomaceæ, illustrated by a large number of coloured drawings, by Prof. Hamilton L. Smith.—On a parabolised gas slide, by Dr. Edmunds.—On the structure and functions of scale leaves of *Lathræa squamaria*, by Mr. Gilbert.—On the interference-phenomena produced by luminous points, by

Mr. Woodall.—On an isophotal binocular microscope, by Mr. S. Holmes.—On the theory of microscopic vision, by Prof. Abbe.—Amongst the objects exhibited were new turntables by Dr. Matthews; slides illustrating invertebrate embryology, by the Naples Geological Station; and several new forms of microscopes and apparatus by Mr. Crisp.

PHILADELPHIA

Academy of Natural Sciences, February 17.—Germination of acorns, by Mr. T. Meehan.

March 2.—Report on plants introduced by means of the International Exhibition of 1876.

March 9.—Dr. H. Allen on the mammary glands of bats.

March 16.—Carcinological notes, No. 4, by J. S. Kingsley.

March 23.—On the gestation and generative apparatus of the elephant, by H. C. Chapman, M.D.

PARIS

Academy of Sciences, June 28.—M. Edm. Becquerel in the chair.—The death of M. Lissajous was announced.—The following papers were read:—Researches on the determination of wave-lengths of calorific rays at low temperatures, by MM. Desains and Curie. A beam of dark heat was sent through a slit to a grating of fine wire, opposite which was a rock-salt lens; beyond this lens the calorific image was formed, and examined with a thermopile. The results mainly agree with those of M. Mouton (by another method).—On the heat of vaporisation of anhydrous sulphuric acid, by M. Berthelot. This vaporisation, about 18°, absorbs − 5·9.—On some general relations between the chemical mass of elements and the heat of formation of their combinations, by M. Berthelot.—On M. Breguet's regulators with vanes, by M. Villarceau. M. Breguet has recently made three apparatus for Lisbon Observatory for determination of personal equations, and the mean errors of isochronism are, respectively, a fifteen-thousandth, an eighteen-thousandth, and a forty-thousandth. It is hoped to go further.—On a new species of the genus Dasyurus, from New Guinea, by M. Milne-Edwards. This is named *D. fuscus*; it comes nearest the Australian *D. hallucatus*.—Craniology of African negro races; dolichocephalic races, by MM. Quatrefages and Hamy.—Possible causes of variation in the results of anthracic inoculation of Algerian sheep; influence of infectant agents; applications to the theory of immunity, by M. Chauveau.—Results obtained in treatment of vines with sulphocarbonate of potassium, by M. Marés.—On the healthiness of the Isthmus of Panama, by M. de Lesseps. Many persons affected by yellow fever have landed there without restriction, but the fever has not at all spread. M. de Lesseps' opinion that quarantines could not prevent epidemics from spreading where their spread was favoured by atmospheric conditions, was called in question by M. Bouley.—On a new form of galvanometer, by M. Gostynski. Proportionality is gained to nearly 90°. The bobbin is continuous, or without slit for passage of an astatic system. A U-piece of aluminium wire hung by a cocoon fibre supports two astatic systems of the same kind, crossed at 45° and connected. A small mirror above the aluminium wire reflects the divisions of a semi-cylindrical scale.—On an apparatus for registering the law of motion of a projectile, &c. (continued), by M. Sebert. This relates to the case of the projectile meeting a sudden resistance, as when entering sand. A plan for recording the law of motion in the entire bore of the gun consists in having two guides and runners in the projectile; one runner is free, and on reaching the end of its course it removes a stop holding the other, which then begins its motion. The resistance of the air in part of the course might similarly be measured.—On the existence in tobacco-smoke of prussic acid, of an alkaloid as poisonous as nicotine, and of various aromatic principles, by MM. Le Bon and Noel. The alkaloid seems identical with the compound collidine, got in distillation of several organic substances.—Researches on the electric properties of collodion, with reflections on the nature of static electricity, by M. Leuro. Collodion in thin sheets is negative with all bodies.—On transcendants which play an important part in the theory of planetary perturbations, by M. Callandreau.—On the application of the theory of sines of superior orders to the integration of linear differential equations, by M. Farkas.—Vibrations on the surface of liquids, by M. Lechat. Lagrange's supposition is incorrect, that below a very slight depth the influence of depth is *nil*.—Relation between the major and minor modes in the gamut agreed according to equal temperaments, by M. Ricard.—Strong and constant voltaic pile, furnishing results susceptible of regeneration by electrolysis, by M. Reynier. The zinc (unamalgamated) is in caustic soda solution, the copper in sulphate of copper solution, separated from the other by a rectangular vessel of parchment paper (several thicknesses). The electromotive force is 1·3 volt to 1·5 volt, according to concentration. The couple is regenerated by passing through it the current of a magneto-machine. M. Edm. Becquerel said the arrangement was not new, his father having used a similar one.—On the mechanical effects in a magnetic core from magnetising action of an electric current, by M. Ader. He has proved that all bars of magnetic nature submitted to a mechanical action of compression, torsion, or traction, tend to recover their original molecular arrangement under influence of the magnetising current.—Independent optical compass for ironclads, by M. de Fraisseix.—Thermal study of alkaline polysulphides, by M. Sabatier.—On the transformation of amylene and valerylene into cymene and benzenic carburets, by M. Bouchardat.—On the etherification of hydriodic and hydrochloric acids, by M. Villiers.—On anhydrous crystallised lime, by MM. Levallois and Meunier. This was found on the walls of a kiln of bauxite, for burning lime.—On the presence of iron in falls of dust in Sicily and Italy, by M. Tacchini. This iron is thought to have come from the Sahara.—On the organisation and the development of Gordians, by M. Villot.—On an acarian destroyer of the gallicolar phylloxera, by M. Pickard.—Zinc: its existence in the state of complete diffusion in all rocks of the primordial formation and in the waters of seas of all ages, by M. Dieulafait.—On the cretaceous formation of the Northern Sahara, by M. Rolland.—On the discovery of new mammalia in the phosphate of lime deposits of Quercy, by M. Filhol.—On the transmissibility of tuberculosis by milk, by M. Peuch. This was proved in pigs and rabbits which drank the milk of a diseased cow. MM. Bouley and Larrey made remarks on the subject.

VIENNA

Imperial Academy of Sciences, April 22.—The following, among other papers, were read:—A new synthesis of sulphydantoïn, by Herr Andreasch.—A new derivative of sulphydantoïn, carbonid sulphonacetic acid, by the same.—On some transformation-products of rufigallic acid and the so-called oxychinon, by Dr. Schreder.—Geological Researches in the Western Balkans and neighbouring region, by Dr. Joule.—Diluvial fauna of Zuzlawitz, near Winterberg, in the Böhmerwald, by Prof. Woldrich.

THE NEW MUSEUM OF NATURAL HISTORY

MR. WATERHOUSE'S new building at South Kensington has, we believe, been formally handed over to the trustees of the British Museum, and as will be seen by their Report, which we give in another column, it is in contemplation, or was so at the time the report was drawn up, to remove several portions of the natural history collections on to the new site during the present year. Up to this time, however, little has been done in the matter. The only beasts and birds to be seen in the new building are those stone images which it has pleased Mr. Waterhouse to place upon the corbels without and upon the pillars within. It is perhaps only fair that if the inside is devoted to *natural* history the outside should be similarly devoted to unnatural history, and architects must have their way. It may also be observed that if the trustees have really taken possession they have sadly neglected their garden department, for the vacant space round the building, which was nicely laid out last year, has been allowed to become overrun with weeds and rubbish. There are two subjects, we believe, which have caused some delay in the proposed removal—the questions of the library and of the mode of government of the new institution. The last-named and most important point being, as the Secretary of the Treasury had stated, still "under the consideration of my Lords," we will make so bold as to tender them a few words of advice on the former subject which also requires their serious attention.

A Library of Reference is, as we need hardly tell the readers of NATURE, an indispensable addition to a Museum of Natural History. No scientific work can be done without it. Of this we may remark the trustees appear hardly to have been aware, if, as we are informed is the case, there is no special room set apart for a library in the new museum. Had the trustees put aside a thousand a year, out of their annual grant of 10,000*l.* for printed books, for this purpose, when it was first determined to remove the natural history collections ten years ago, there would have been by this time in existence a library fully adequate for the purpose. But no provision of this sort appears to have been thought of, and it is only within the last year or so, when the building is ready and the time is come to remove the natural history collections into their new quarters, that any application for the necessary funds to buy a library has been made to the Treasury.

Now the special function of the Secretary of the Treasury is, as everybody knows, to keep down expenditure. We need not, therefore, be surprised if when the request was made to him for 30,000*l.* to buy a library of natural history books Sir Ralph Lingen stood rather aghast, and demanded time to consider the subject. But even were this great official most benevolently disposed towards the new natural history museum and ready to produce the sum demanded at once it would not by any means enable the trustees to meet the object in view. It is by no means simply a case of going into the market and ordering all the books required of the first bookseller. The greater number of the works required are out of print, and only to be picked up at scattered intervals at second-hand shops. To endeavour to purchase them all at a moment's notice would be simply useless. This is another reason why the policy above recommended of collecting the required library by slow degrees should have been adopted.

There is now in fact only one way out of the difficulty. It is a very simple one, but we fear the trustees will not like it. The naturalists and students of the British Museum have hitherto had the use of the Great National Library, which contains all the necessary scientific books. Let these necessary books be removed along with the collections to South Kensington, not as a *gift*, but as a *loan* to the new institution. Let the trustees devote an annual sum of such an amount as they can conveniently employ to their redemption—that is, to the purchase of second copies of these scientific books. As soon as the duplicates are received at South Kensington let the originals be returned to the British Museum. Thus the Great National Library will ultimately recover its own completeness, while at the same time the new museum of natural history at South Kensington will be able to start work with a perfect library—which could in no other way be provided for it. Moreover instead of having to find some 25,000*l.* or 30,000*l.* at the present moment, the Treasury will be able to spread the necessary expenditure over several years, during which it is certain that many of the rarer volumes unattainable at the present moment will come into the market. The only objection to this plan that we can see is that it will be sometimes necessary to refer an applicant for a particular volume at the reading-room of the British Museum to South Kensington. But when it is once understood that the natural history books are at South Kensington people will very soon learn to go there for them.

The real difficulty in the present situation is that the control of the whole museum is in the hands of the principal librarian, who naturally enough prefers the interests of the library to that of the natural history. He is glad enough to get rid of the beasts and birds, but when you ask him to give up, even temporarily, a portion of the books it is quite another question. Very few of the trustees who are nominally his masters care anything for natural history, so that from that quarter no intervention can be looked for in favour of the scheme we have put forward. The only way in which it can be carried out is by the *vis major* of the Treasury, which, as the plan is not only advantageous, but also economical, should surely be exerted in its favour.

If the Government had taken the advice of the Duke of Devonshire's Commission, and handed over the natural history collections to a director under the control of the Department of Science and Art, there would have been some one sufficiently interested to make a stir on the subject. As the matter now stands the principal librarian can of course do as much as he pleases, and will, no doubt, keep his books in Bloomsbury as long as possible.

ELEMENTARY EDUCATION

LORD NORTON and his friends seem determined to take every opportunity of hunting down the present system of education in Government elementary schools.

Last week the subject was again introduced in the House of Lords, with, as before, an unsatisfactory result. The action of Government with reference to Scottish educational endowments is rather an impressive commentary on the conduct of the obstructives who are so anxious to reduce the standard of education in England. The effect of the Scotch measure will be greatly to extend the means of education for those who usually attend Board Schools, placing as it does at their disposal the education to be obtained in secondary schools, an advantage, we should think, likely to be largely taken advantage of. Until some similar course be taken with reference to England, where so many valuable educational endowments have been diverted from their legitimate purpose, it seems to us cruel rigidly to limit the function of elementary schools in reference to pupils of exceptional promise. Still more cruel is it to turn out the great bulk of the children with an education quite unworthy of the name, and which renders them little better fitted to cope with their surroundings than if they were entirely unlettered. It is our bounden duty, since we insist on keeping children at school till a certain age, to do the best we can for them; and to turn them out equipped with nothing more useful than the three R's is a mere mockery of education. If reading, at all events, is to be a really useful acquisition, let us make them understand that there are things quite as wonderful and quite as well worth reading about as the horrors of the penny dreadfuls. Many of these children, the working men and working women of the future, will have but little time to put the three R's to much use, whereas if well grounded in the elements of one or two of the most useful of the sciences, they will have a continual source of pleasure within themselves, requiring neither books nor pens, but only the exercise of thoughtful observation. That education is admittedly the best which enables one to cope most successfully with the difficulties of his surroundings, and we cannot see how any candid man will deny that for this purpose an accurate training in the science of common things is worth all the books in the world. That the Government system as at present established commends itself to the sense of the people is clear from the fact that Government schools are practically killing all competitors. As to the dread of the over-education of the people, this is a bogy which only needs to be stared at to vanish. Do we find any lack of men and women to do all sorts of work in Germany or France, or in any other country where the people have a really substantial education? In nearly every county of the kingdom are local scientific societies, many of which are composed mainly of working men who have educated themselves into whatever they may know of science; but we have yet to hear that they are more discontented with their position than unlettered Hodge. The real truth is, as is too clearly shown on the Continent, the better educated the working man is, the better workman does he turn out to be. The great mistake is to confound a smattering with a grounding, and this, it seems to us, is the mistake made by Lord Norton and those who side with him, and possibly may account for the opposition to the Fourth Schedule. The exclusive use of such a reading-book as Lord Norton threatens to compile would be the best help to a smattering education; a very few hours a week devoted to a few well-selected experiments, the judicious use of specimens and diagrams, a little training of the observing faculties of children, and the systematic teaching of the great elementary facts of one or two sciences would be a welcome relief to the pupils, and would do far more for their real education than a library of reading-books.

Sir John Lubbock has given notice that he will shortly introduce the subject into the House of Commons; it is inconceivable that that body will permit anything like retrogression in the matter of education; they cannot do so without being liable to the imputation of class legislation. At the best, our working men and working women, it must be confessed, have a hard life of it, many of their hardships resulting from ignorance of the commonest laws and facts of nature. If we wish to make them contented with their lot, let us lighten it by enlightening their minds and giving them the means of making the best of their circumstances. It is against the teaching of all history to maintain that what the retrogressionists are pleased to call over-education will lead to all sorts of political and social evils. It is, history tells us plainly enough, the ignorance, and not the enlightenment, of the people that should be feared. The better educated we are all round the more likely are we to keep our foremost place among nations who have already, solely by the superior education of all classes, got ahead of us in some important respects, and the more likely are we to continue to advance by gradual evolution instead of by violent revolution, which always requires a large substratum of ignorance to work with.

ARGENTINE ENTOMOLOGY

Hemiptera Argentina enumeravit speciesque novas descripsit Carolus Berg (Curonus). Bonariæ, *ex typographiæ* Pauli E. Coni. Hamburgo, *in biblopolio gassmannii.* (Frederking et Graf, 1879.)

ENTOMOLOGY is finding a new centre in Buenos Ayres; synchronous with the first part of Dr. Burmeister's treatise on the Lepidoptera of the Argentine Fauna, lately noticed in these columns, has appeared the above work on the less popular and very much less known order Rhynchota. In common with many entomologists, we use this last term rather than that of Hemiptera, as written by our author, for the following reasons. Linnæus founded the order Hemiptera, but included therein non-allied insects, to which the name Orthoptera was ultimately applied by Olivier, whilst Fabricius was the first to separate the true "bugs," under the name of Ryngota, which was afterwards linguistically purified into Rhynchota. Not only, however, did the great Swedish naturalist first propound the order Hemiptera, but we are also indebted to Sweden, in the person of the late Prof. Stål, for gathering together with critical and exhaustive care the descriptive work of an intervening century, and, by the help of a splendid collection formed at Stockholm, reducing the classification to a system, and making the study of the order a possibility. It is this system which is followed by Prof. Berg in the modest work under notice, which is not a monograph, but rather an enumeration of the known species, accompanied by descriptions of new ones. The work is therefore special in its character and classificatory in its

aim; no biological conclusions are attempted nor structural details given, save such as appertain to generic or specific diagnosis. Its value therefore is to the student of the local fauna and the generaliser in the study of geographical distribution.

The work of course must be considered to a certain extent as introductory only; many species will necessarily be discovered and added to the fauna, whilst of those described it is equally probable that some will prove of synonymic value only. The last conjecture becomes almost a certainty when an estimate is made of the difficulties under which Prof. Berg must have worked, so far removed from all the large collections, identifying or separating frequently by the help of poor descriptions, with the impossibility of examining the original types. His descriptions however are very clear, and have as a rule appended the *differentia specifica* from a nearly allied form. It is much to be regretted that this course is not more usually followed by some other entomologists, and it would almost appear in many cases that from being so frequently told by the biological philosopher that descriptive is the lowest form of scientific work, that the describers themselves in despair had done the work in the very lowest manner. It was well said that "some see differences and no resemblance, others resemblance and no difference, whilst some again can see neither the one nor the other," and thus the help acquired from comparative diagnosis appended to an exhaustive description becomes the more necessary when it is not possible to give a figure of the species. Whatever conception may apply in the mind of the individual worker as to the much vexed term "species," it is at least to be expected that the limits of variation can only be estimated by one who has thoroughly studied a group and knows some little of their life histories. It is in this field that the specialist should really be considered a prophet, and in entomology there are not only families but even genera which are so peculiar and unique in the variation of their species that the *variable* might with advantage be added to the *structural* diagnosis. In the Rhynchota this is extremely applicable, even structural characters which are constant and specific in one genus being variable and of no specific value in another, whilst colour and size, generally of no moment, are in some few instances beacons which denote specific differentiation.

In studying a work of this nature we become sensible of the vast unexplored field of entomology. We here possess the identifications and names of the forms constituting a fauna, but by what methods its homogeneity was secured remains still to be discovered. Which species or genera are even pleistocene forms which have been introduced by man, or by other means of involuntary migration, we have at present no record. The interdependence on the botanical geography of the district must always be a factor in the distribution of the non-carnivorous forms of the Rhynchota, and the meteorological conditions of a country will in future be more studied by entomologists who are investigating local faunas.

Prof. Berg has introduced a valuable addition to his work in the descriptions, where possible, of immature forms. Larvæ in this order are most difficult to adequately describe, and we may hope that the author in some subsequent publication may be able to give us illustrations of the same.

W. L. DISTANT

THE HUMAN VOICE

The Mechanism of the Human Voice. By Emil Behnke, Lecturer on Vocal Physiology at the Tonic Sol-fa College. (London: J. Curwen and Sons, 1880.)

THE object of this little book is to give singers a plain and comprehensible view of the musical instrument on which they perform. The author seems to have succeeded in this attempt remarkably well. He has evidently had much practical work himself, and has especially set himself the task of examining the action of the vocal organs during singing by means of the laryngoscope, and his record of his own experience in acquiring the use of that beautiful instrument is not only interesting but of much practical value. The last section of the book is devoted to the teachings of the laryngoscope, as to the action of the vocal ligaments in producing voice, with especial reference to the so-called registers. "A register consists of a series of tones which are produced by the same mechanism," is his definition (p. 71), which is new and complete, and he proceeds to explain the different mechanism of each kind of register as actually observed on singers. There are some good remarks on breathing (pp. 17-22). All information is given throughout in clear, intelligible language, and illustrated by fourteen woodcuts (not all original), which are purposely rather diagrammatic in character, in order not to confuse the eye with too many details at a time, but every essential point is gradually introduced. The author seems to have been diligent in the consultation of authorities as well as in practical work of his own, and the book may be safely recommended to all singers, and others who are desirous of knowing how vocal tones are produced.

There are a few things which may be pointed out in the hope that they will be corrected in a second edition, which ought to be soon required. On p. 4 the author implies that former musical pitch was a major to a minor third flatter than at present. For all music now sung the difference was scarcely more than a semitone. On p. 30, and again on p. 70, he says: "The vocal ligaments, by their vibrations, cut the stream of air passing between them into regular waves." It is difficult to see how these words convey, even metaphorically, a correct conception of what happens. "To cut a stream into regular waves," is not a very intelligible operation. The expression should certainly be altered, and a few lines added to convey the full notion. On p. 37 the author seems to be wrong in considering that glottis (or "tongue" in the singular) refers properly to the vocal ligaments (or "tongues" in the plural). It is merely what he terms the "chink," or the tongue-shaped space between the vocal ligaments as shown in Pl. X. A. He also omits to notice especially the cartilaginous glottis between the pyramids (arytenoids), although it appears in Plate X. C, and XIV., XV., XVI. On p. 44 he gives as a function of the pockets (ventricles of Morgagni) that "they allow the stream of air which has just been converted into tone to expand sideways, thereby materially adding to its resonance." The whole phrase is confused and should be entirely re-written; the

conversion of a "stream" into a "tone," and "adding" to the "resonance" of such a converted stream, is very slipshod writing. On the whole matter of resonance (p. 46) the writer is unsatisfactory. He does not include the cavities between the vocal ligaments and the lid (epiglottis) among the resonating chambers, except in the objectionable passage just cited, and he does not enter into the question of the modification of quality of tone by means of these resonances. By some accident in engraving Plate XIII. the letter w is placed on the windpipe, as well as on the cartilages of Wrisberg, and the vocal ligaments are not distinct enough. All the figures, XIII. to XVI., seem to be copied from the English edition of Madame E. Seiler's "Voice in Singing." It is a pity to waste space in such a little book on controversy. It was hardly necessary to quote Madame E. Seiler at length (pp. 81-90), and then controvert many of her statements. This only tends to confuse the learner. The result should be given from the author's own observations, and then, if desired, the points of difference might be explained in a note. Similarly for the controversy about the action of the "wedges" (cuneiform cartilages) on p. 45, which has no interest or use for a beginner. The space devoted to controverting Mr. Lunn's "Philosophy of Voice" (pp. 52, 69, 70), and to Mr. Illingworth's "hazelnut" theory of the "pockets," and other bits of controversy with Miss Sabilla Novello (p. 30) and Dr. Garrett (p. 32) might also have been saved with advantage.

It takes much space to point out a few minor blemishes that scarcely detract from the general merits of the book, which is clearly the result of much real work and careful observation.

OUR BOOK SHELF

Keith Johnston's Illustrations of Electricity and Magnetism. By W. Lees, M.A. (W. and A. K. Johnston, Edinburgh and London.)

MESSRS. W. and A. K. JOHNSTON have begun an excellent work in issuing these four sheets of diagrams in illustration of the fundamental experiments of electricity and magnetism. The subjects are well chosen, and with hardly any exception well drawn and coloured. They will be welcomed by teachers of science classes in schools for their clearness and general excellence. Mr. Lees, who has prepared them, has also issued a specially-written "Handbook" to accompany each sheet. Of these handbooks—though perhaps useful for such pupil-teachers as may have the misfortune to be set to teach a subject in which they have themselves never made a single experiment—the less said the better. The writer of them is in bondage to the ideas of half a century ago. Take as a specimen the following statement concerning the Leyden jar:—"Suppose, then, the accumulation of electricity in the jar to proceed, the quantity of free electricity in the inner coating goes on also increasing, *until the density of that electricity becomes the same as the density of the electricity of the prime conductor.*" The italics are the author's own! This is no more absurd, as a scientific statement, than it would be to say that when a dock-sluice is opened the water rushes in from the higher level until the muddiness of the water inside is as great as the muddiness of the water outside; for the electric equilibrium of two conductors no more depends upon the *density* of their respective charges than does the flow of water upon its degree of turbidity. Yet the writer of this amazing sentence styles himself "Lecturer on Natural Philosophy, Edinburgh"! For the sheets of diagrams themselves we have nothing but praise.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

A Fourth State of Matter

MR. CROOKES has given us optical evidence of the existence of matter in a state of tenuity known hitherto only indirectly, and considers himself warranted in affirming the discovery of a fourth or ultra-gaseous condition; yet it can scarcely be conceded that he has demonstrated the truth of his views, or that his recent exposition of them has strengthened his position or satisfied the doubts of the sceptical. It is simply a question of the use or misuse of certain specific terms, and it is difficult to follow the logic which justifies the creation of a "fourth state" by the attribution of properties not differing essentially from those of matter in its normal condition. Before his contention be granted it should be proved that the substance under experiment possesses properties exclusively and inalienably its own; as rigidly defined as those which distinguish the solid from the liquid, or the latter from the gaseous.

By the abstraction from his experimental chamber of a large portion of its contents he has enlarged the interstitial spaces of the residual gas, and thus amplified the mean free path of molecular vibration from some millionths of an inch to several inches; but beyond this extension of the path of oscillation there seems nothing to warrant the opinion that the residual gas is essentially other than it was before.

If this amplification of the molecular path be the feature relied on for justifying the term "fourth state"—and this seems the only inference—then further travel in this direction brings us to a point easily within our conception, where the contents of the experimental chamber shall not exceed one or two molecules; and it becomes interesting to know if Mr. Crookes would then add a *fifth* to the other states of matter. To do so would seem the inexorable outcome of his reasoning, and inevitably resolves the question into one of the numerical contents of the chamber; and it rests with him to define the precise point where the ordinary conditions cease, and the *ultra-gaseous* commences.

In gases, whether at the normal density, or rarefied to 3 mm., we have an unbroken continuity of condition; which, contrasted with the solid and liquid forms of matter, is noticeable for the bsence of any point whence a new state can be said to originate: would Mr. Crookes assign a vacuum of 0·999 mm. or one of 0·00003 mm. as the critical point in the attainment of his "fourth state" or some intermediate density?

Again, has Mr. Crookes fully recognised the distinction between the properties of matter *per se* and those which are referable to electrical agency as revealed by the experiments of Messrs. De La Rue and Müller, where the projection of molecules against the walls of the containing vessel is attributed to electrification; or, further, the fact that a tenuity approaching that attained in his experimental chambers has been long familiar to us in the case of steam of very high pressure?

Whatever may be the solution of our speculations regarding the ultimate condition of matter, opinion seems unanimous that the concrete form in which it is known to us consists of an aggregation of particles having immutable properties and composition, gaseous bodies being definite molecular groupings of such particles; and if such be the case, and the chemical character of the contents of Mr. Crookes' experimental chambers remained unaltered, it is difficult, if not impossible, to conceive the existence of any further condition other than that produced by the breaking up of the molecule into its component atoms.

London, July 9 GEO. E. NEWTON

Permanent Record of Foucault's Pendulum Experiment

SOME four years since, while arranging a Foucault's pendulum for use in the class-room, it occurred to me to endeavour to obtain a permanent record of the experiment, and as the results were very good, and the method simple, they may be interesting to others.

The pendulum used was sixteen feet long, the height of my lecture-room at the Massachusetts Institute of Technology, and

consisted of a cannon-ball weighing about 5 lbs., suspended by a fine steel wire, which at its upper end passed through a hole drilled in an iron plug. The pendulum would continue to vibrate for sixteen or eighteen hours after being set in motion. After obtaining satisfactory results by using a ring of sand in the ordinary manner, a very stiff bristle was attached to the terminal spindle, and under it was placed a thin smoked-glass plate. The resistance was too great to allow the bristle to strike against the plate at each vibration of the pendulum, so that the device was adopted of fixing the plate upon a heavy brass disk capable of being raised or lowered by levelling-screws. This was placed under the pendulum before the latter was set in vibration, and then carefully raised until the bristle scratched its trace on the smoked-glass plate. After two or three oscillations of the pendulum the plate was lowered, great care of course being taken to avoid all possibility of rotation during this operation. At the expiration of fifteen, thirty, or sixty minutes it was again raised, and this process was repeated as often as desired. The inclination of the tracings was beautifully shown, and its amount agreed exceedingly well with that given by theory. With a heavier ball and longer wire even better results might have been obtained, but the motion of the pendulum used was but very slightly interfered with by the friction of the bristle. I should not omit to mention that the details of the experiment were carried out by Mr. F. W. Very, then a student at the institute. CHAS. R. CROSS

Boston, Mass., June 19

The Freshwater Medusa

IN NATURE, vol. xxii. p. 218, Prof. Allman by mistake attributes to me the conclusion that Limnocodium has no marginal canal, and that its radial canals are not pervious. A reference to NATURE, vol. xxii. p. 147, will show that in my first publication on the subject I gave as a character of the new genus "Radiating canals 4, opening into the marginal canal. Marginal or ring canal voluminous." I made the same statement in my communication to the Royal Society on June 17, and have not since deviated from it. E. RAY LANKESTER

Artificial Diamonds

THE process of building up tubes, which Mr. Mallet has been so kind as to suggest to me through your valuable journal, has been tried, but was unsuccessful through the same defect as caused the failure of many of my other experiments, namely, leakage without bursting. Some of the tubes found empty would bear, when cold, a pressure of ten tons on the square inch without leaking, showing that the gases escaped through the porosity of the iron at a high temperature. Hydrogen and hydrocarbons seem to go through iron at a red-heat very easily, and the direction in which I am working is to obtain an impervious coating, or a method of "clogging" the iron, as seems to have some-times taken place in the carbon experiments.

Experiments conducted since the reading of my paper have convinced me that the crystallisation of silica and alumina may yet be carried out with ease and certainty, and when I have rendered one of these processes a commercial success the experience gained in daily manufacturing operations will enable me to attack the carbon problem with much more certainty of obtaining definite results.

As I shall be writing an account of this work in the autumn I shall feel greatly indebted to any of your readers who, if they come across any not widely known experiments in this direction, will kindly communicate with me, so that I may have all the work done in this direction before me. Suggestions such as Mr. Mallet's are valuable to any worker, as the reactions of one brain must always be somewhat similar unless outside stimuli give new directions to its activity. I am always therefore thankful for either suggestion or corrections. J. B. HANNAY

Private Laboratory, Glasgow

Temperature of the Breath

THE average temperature of the interior of the human body, according to our best authorities, is 98°·6 F. What is the temperature of the breath? It might naturally be supposed that its temperature was the same as that of the interior of the body, or lower, if it is derived from the lungs, into which it is drawn from the cold outer air. But is this so?

The temperature of my body, as shown by the thermometer in the axilla and mouth, is normal, *i.e.*, about 98½°. On rising in the morning, before dressing or eating, I take the thermometer, wrap it up tightly in several folds of a silk handkerchief, and breathe upon it (expiring through the silk immediately over the bulb of the thermometer and inspiring by the nostrils). After five minutes of this operation I examine the thermometer, and find that it indicates a temperature of 106°·2. At 7 p.m., after brisk walking exercise, having eaten nothing since breakfast except a spoonful of boiled rice at 1 p.m., and having drunk nothing but half a tumbler of water and a mouthful of ginger-beer, I take the temperature of my breath in the manner described, for five minutes. I find the thermometer indicates 107°. Again, immediately after dinner, at which only water was drunk, the thermometer shows my breath to have a temperature of 108°. At other times the thermometer will not rise under apparently the same conditions higher than 102° to 105°. A temperature of 109° was observed by the correspondent of an American journal, but he does not mention under what circumstances this occurred.

How is this high temperature produced? It cannot, as a friend suggested to me, be caused by the condensation of the moisture in the breath by the silk handkerchief, for if the temperature of the breath as it issues from the lungs be the same as that of the lungs themselves, *i.e.*, not exceeding 99°, the silk, soon becoming much hotter, would rather tend to volatilise than to condense the moisture of the breath. Is it caused by the friction of the breath upon the fibres of the handkerchief? I know of no observations to show that a high temperature would be so caused. Is it the actual temperature of the breath as it issues from the lungs? If so, then it is by the breath that the system gets rid of its superfluous caloric. For this elevated temperature is not communicated to the blood oxygenated in the lungs; the blood in the left ventricle of the heart (which receives this oxygenated blood) being, according to some physiologists, lower in temperature than the blood in the right ventricle, which has not yet entered the lungs.

The few experiments I have made seem to show that the temperature obtained as above described is higher when the surrounding air is warm than when it is cold. This looks as if more caloric passed off by the breath when less can escape from the general surface of the body.

How these high temperatures are produced in the lungs, if they are developed there, is a mystery. Perhaps some of your readers may be able to explain.

53, Montagu Square, May 27 R. E. DUDGEON

Reversals by Memory

I SHOULD much like to know if it be a common thing for people to *reverse* the positions of objects in the memory. An artist, on returning from the National Gallery, painted the *Téméraire* from memory. Taking his picture to compare it with Turner's, he found to his surprise that he had reversed the positions of the ship, tug, sun, &c. His daughter tells me that if she wants to refer to a passage in a book she as often looks for it on a left-hand page, while it is on a right-hand page, or *vice versâ*. Another lady, on looking at a wood-engraving made from a sketch which she had seen some time previously, asked if the engraver had not reversed everything? These are the only cases known to me.

Is the following universally true?—

Let some one write with a blunt instrument the letter P on your forehead, or anywhere on the front half of the head from ear to ear, and the P must be written backwards for *you* to "see" it correctly. But if it be written anywhere at the back of the head, it must be written correctly both for you and the writer to read it. The change takes place abruptly in a line over each ear. GEORGE HENSLOW

Toughened Glass

THE night before last a lady of my family emptied a paper powder composed of 7½ grains of carbonate of potash and 7½ grains of carbonate of soda into a tumbler of what is called *toughened glass* less than half full of cold water. After stirring the mixture she drank the contents, leaving a silver tea-spoon in the tumbler, and then placed the empty tumbler on the table by her side within perhaps a foot of a burning duplex lamp. About five minutes afterwards a sharp explosion occurred, which startled

all in the room. We found the tumbler shattered into fragments, the body of the glass ripped up, as it were, into several large, irregular-curved pieces, and the bottom of the tumbler broken into small pieces more resembling thick rough ice than anything else. *Query*: Was the explosion caused by the inherent properties of the toughened glass, or by the contact of potash, soda, the silver spoon, and proximity to a lamp, the heat from which was very slight, indeed scarcely perceptible to the hand at the spot where the tumbler stood?

The accident might have been very serious, for pieces of the glass flew to within a very few inches of the lady's face. A solution of the cause of the explosion is therefore of considerable importance to all who may have occasion to use vessels of this peculiar glass. NOBLE TAYLOR

Sunninghill, July 7

Great Meteor

A METEOR of extraordinary brilliancy was seen on Friday, July 9, about 8·20 p.m.—almost in full daylight, the sun having only just set—by the Rev. Mr. Lloyd-Jones, who kindly took me to the place of observation and gave me the following particulars:—

The meteor was quite half as large as the full moon, of dazzling light-blue colour. It moved slowly in a path inclined about 10° to the horizon, from left to right, and emitted a train of ruddy sparks. Mr. Lloyd-Jones was looking in the opposite direction, and had time, after his attention was called to it by a friend, to turn round and see the last 10° of the path. The total duration may have been ten seconds, and could not have been less than five, the meteor dying out slowly. The point of disappearance was carefully noted and referred to some trees about 200 yards distant. I afterwards found it to be in true azimuth N. 69½° E., altitude 9°. No detonation was heard. The place of observation was about two-thirds of a mile east of the Royal Observatory, Greenwich. G. L. TUPMAN

Iron and Hydrogen

MAY I be allowed to point out that the question of the occlusion of hydrogen in steel, and its influence in hardening, has been discussed by Mr. Wm. Anderson in his report to the Committee of this Institution on the Hardening, &c., of steel.

At the last meeting of this Institution Prof. Hughes stated that his experiments did not support the hydrogen theory, but rather the view that hardened steel was an actual alloy of carbon and iron, unhardened steel a mixture only. I may add that experiments are now in progress, designed to test the truth of this latter view. WALTER R. BROWNE
Secretary

Institution of Mechanical Engineers, July 12

The Stone in the Nest of the Swallow

THE swallow stone is the agate pebble, called in French *chélidoine*—the name given to the chalcedony (NATURE, vol. xxi. p. 494), but the same virtue is attributed to the swallow herb. This is the *Chelidonium majus*, about which Britten and Holland, in their "English Plant Names," give the following quotation from Lyte:—"Chelidonium, that is to say, swallow-herbe, bycause (as Plinie writeth) it was first found out by swallowes and hath healed the eyes and restored sight to their young ones that had harme in their eyes or have bene blinde."

Littré, in his great *Dictionnaire*, gives two quotations, in which *Chélidoine* is used in a botanical sense:—

> "Se vus avez as oils manjue
> Dunc prenez celedoine et rue."
> *MS. St. Jean, 13th century.*

> "Aussi les guerit le jus de cheledoine, le lait de tithymal."—
> *Paré, v. 21, 16th century.*

He also gives its meaning as the name of a precious stone, and adds: "Petits cailloux appartenant aux agates, on dit aussi pierres d'hirondelle." With respect to its etymology he says he derives it from "χελιδόνιον, de χελιδών, hirondelle, à cause qu'on disait que l'hirondelle se servait de cette plante pour rendre la vue à ses petits." Fern Bank, Higher Broughton, Manchester

THE CARIBBEAN SEA

THE Coast Survey steamer *Blake*, Commander J. R. Bartlett, U.S.N., Assistant Coast Survey, recently returned from a cruise taking soundings, serial temperatures, &c., in the course of the Gulf Stream, under instructions from C. P. Patterson, Superintendent Coast and Geodetic Survey, has brought very interesting data in regard to the depths of the western portion of the Caribbean Sea.

The depths and temperatures obtained last year in the "Windward Passage" between Cuba and San Domingo were verified, and a few hauls of the dredge taken directly on the ridge in this passage. The data obtained render it very probable that a large portion of the supply for the Gulf Stream passes through this passage, and that the current extends in it to the depth of 800 fathoms. A few lines of soundings with serial temperatures were run from Jamaica to Honduras Bank, *viâ* Pedro and Rosalind Banks, and it was found that the temperature of 39½°, obtained at all depths below 700 fathoms in the Gulf of Mexico and the Western Caribbean, could not enter through this portion of the sea. But the temperature at the depth of 800 fathoms on the ridge in the "Windward Passage" between Cuba and Hayti was found to agree with the normal temperature of the Caribbean and Gulf of Mexico, viz., 39½°. Soundings were taken between Hayti and Jamaica, developing a general depth between these islands not exceeding 800 fathoms, except where broken by a remarkably deep channel connecting the waters of the main Caribbean south of San Domingo with those north of Jamaica. This channel runs close to Hayti with a greatest depth of 1,200 fathoms, and a general depth of 1,000 fathoms. Its course is northerly along the western end of Hayti, where it does not exceed a width of 5 or 6 miles; thence westerly, south of Navassa Island, with a tongue to the northward between Navassa and Foxmigas Bank, and another to the westward between Foxmigas Bank and Jamaica.

A line of soundings was run from San Iago de Cuba to the east end of Jamaica, where a depth of 3,000 fathoms was found 25 miles south of Cuba. This deep place was found by subsequent soundings to be the eastern end of an immense deep valley extending from between Cuba and Jamaica, to the westward, south of the Cayman Islands, well up into the Bay of Honduras. The Cayman and the Misteriosa Bank were found to be summits of mountains belonging to a submarine extension (exceedingly steep on its southern slope) of the range running along the south-eastern side of Cuba. This deep valley is quite *narrow* at its eastern end, but widens between the western end of Jamaica and Cape Cruz, where the soundings were 3,000 fathoms within 15 miles of Cuba, and 2,800 fathoms within 25 miles of Jamaica. Near Grand Cayman the valley narrows again, but within 20 miles of this island a depth was found of 3,428 fathoms. The deep water was carried as far as a line between Misteriosa Bank and Swan Islands, with 3,010 fathoms within 15 miles of the latter. On a line between Misteriosa Bank and Bonacca Island there was a general depth of 2,700 fathoms, and a depth of over 2,000 fathoms extended well into the Gulf of Honduras. Between Misteriosa Bank and Chinchorro Bank the soundings were regular at 2,500 fathoms. North of Misteriosa and Grand Cayman, to the Isle of Pines and Cape San Antonio, the soundings were generally 2,500 fathoms. The serial temperatures agree, in relation to depth, with those obtained in the Gulf of Mexico, by Lieut. Commander Sigsbee, and in the Eastern Caribbean by Commander Bartlett; decreasing from the surface to 39½° at 700 fathoms, or less, and constant at that temperature for all depths below 700 fathoms. At greater depths than 600 or 700 fathoms the bottom was always found to be calcareous ooze composed of Pteropod shells with small

particles of coral. These Pteropod shells, as noted in previous expeditions by different nations, appear to be an important factor in the determination of the movements of great bodies of sea-water. The ridge at the "Windward Passage" is bare coral rock, and on the south side the Pteropod shells were found to be much more numerous than to the northward of the ridge. Soundings and serial temperatures being the special objects of the course, dredgings were only incidentally attempted for the purpose of reconnoitring, as it were, the ground, and it was found that the area passed over was not nearly so rich in animal life as that in which dredgings were taken last year under the lee of the Windward Islands at the eastward of the Caribbean Sea.

The development of the extraordinary submarine valley in the western Caribbean Sea is a matter of great interest considered as a physical feature. This valley extends in length 700 statute miles from between Jamaica and Cuba nearly to the head of the Bay of Honduras, with an average breadth of 80 miles. Curving around between Misteriosa Bank and Yucatan, and running along between Cuba and the ridge of the Caymans for a distance of 430 miles, with a breadth of 105 miles, it covers an area of over 85,000 *square miles*, having a depth nowhere less than 2,000 fathoms, except at two or three points (the summits of submarine mountains), with a greatest depth, 20 miles south of the Grand Cayman, of 3,428 fathoms, thus making the low island of Grand Cayman, scarcely 20 feet above the sea, the summit of a mountain 20,568 feet above the bottom of the submarine valley beside it—an altitude exceeding that of any mountain on the North American continent, above the level of the sea, and giving an altitude to the highest summit of Blue Mountain in Jamaica, above the bottom of the same valley, of nearly 29,000 feet, an altitude as great, probably, as that of the loftiest summit of the Himalayas above the level of the sea.

For the deepest portion of this great submarine valley the Superintendent of the Coast and Geodetic Survey has adopted the name of "Bartlett Deep."

ALBANIA AND THE ALBANIANS

ABOUT the dawn of authentic history the Balkan peninsula seems to have been mainly occupied by two kindred Aryan peoples—the Hellenes in the south, the Thrako-Illyrians in the north. Since then, or, say, for some 3,000 years, this region has been swept by more numerous tides of migration than almost any other country on the globe. Some of these waves, such as those of the Kelts 300 years before, and of the Goths 400 years after, the Christian era, receded without leaving any permanent traces behind them. Some, such as the Romans, are still represented by the Dako-Rumanians of the Danubian principalities and their southern kinsmen, the Zinzars or Kutzo-Vlachs of the Pindus range and Thessaly. Others, such as the Ugrian Bulgars, have been absorbed or assimilated to the Slaves, intruders like themselves, while others again have either resettled the land, as, for instance, the Serbo-Croatians, or else, like the Osmanli of Tûrki stock, have seized the political control without making any serious attempts at colonisation. The result is a condition of things absolutely without a parallel elsewhere—an utter chaos of races, languages, religions, a clash of social interests and national aspirations, which has long threatened the peace of the world, and the means of reconciling which the wisest heads have hitherto failed to discover.

But beneath and above all these strange vicissitudes and endless complications the two relatively aboriginal elements of the population still here and there hold their ground. The Hellenes have doubtless been largely Slavonised almost everywhere on the mainland,[1] although even here the old Dorians are still believed to survive in the Zakonians of the Spartan hills and the Mainotes of the Tænarum peninsula. The northern branch, also, of what has not inaptly been called the Thrako-Hellenic family still predominates, and even retains a certain vitality, in the Albanian highlands. Thracians, Pæonians, Dardanians, Mœsians, and all the other eastern and northern members of the race have long been extinct as independent nationalities; but the Illyrian or western branch still continues to be represented by the Shkipetars in their original home, on the south-eastern shores of the Adriatic.

[1] "La Grèce devint une Slavie, et l'idiome général fut une langue Slave" (E. Reclus, i. p. 52).

The term Albania, it is needless to say, possesses no administrative significance, nor even any very strictly-defined geographical limitations. It is purely an ethnographic expression, though even in this sense no longer quite conterminous with the people from whom it is derived. In its widest extent Albania stretches from the Montenegrin and Servian frontiers southwards to Greece, and from the Pindus, Grammos, and Char Dagh ranges westwards to the coast. Within this area are comprised three nearly coincident physical and ethnical divisions, for everything here seems to run in triads, so that the more technical data necessary to understand a somewhat intricate subject may be conveniently summed up in the subjoined series of triplets:—

I. THREE NATURAL DIVISIONS.—1. *Upper Albania*, reaching as far south as the river Shkumbi, about 41° N. lat., and mainly comprised in the Drin basin. 2. *Central Albania*, between the Shkumbi and Voyussa rivers, mainly in the Ergent basin. 3. *Lower Albania*, or *Epirus*,[1] thence to the present Greek frontier (Akarnania).

II. THREE POLITICAL DIVISIONS.—The Turkish vilayets of *Isgodra* (*Skutari*), *Monastir* or *Qosowa*, and *Yanina*, the two former stretching eastwards beyond the actual limits of Albania proper, most of the third awarded to Greece by the Berlin Conference, which has just concluded its labours in connection with the settlement of the new Turko-Greek frontier.

III. THREE GREAT LAKES.—Those of Skutari, Okhrida, and Yanina, convenient landmarks, a curve described through which from about Antivari to Prevesa, both on the coast, will roughly mark the inland frontier line of Albania proper.

IV. THREE MAIN RACIAL ELEMENTS.—1. The old Thrako-Illyrian, now everywhere largely intermingled with 2, The Slav (Serbo-Croatian branch) in the north, and with 3, The Hellenic (Dorian branch) in the south.

V. THREE COLLECTIVE ETHNICAL OR NATIONAL NAMES.—1. *Shkipetar*, the most general national appellative of the people, whence Shkiperia (in the Northern dialect Sipenia) the country, and Shkipeia, the language; from root Shkip, Shkup = rock; compare Greek, σκόπελος; Latin, *scopulus*; and Ptolemy's old Dardanian town of Skupi. Hence Shkipetar = hillmen, highlanders, according to the most accepted interpretation. 2. *Albanian*, unknown, at least in this form, to the natives, yet of respectable antiquity, and now mainly current in the west of Europe and Greece. The word is usually referred to the Keltic or Aryan root *alb*, *alp* = height, snowy crest, and has been connected with Ptolemy's Albani, a small tribe whose chief town was Albanopolis, north-west of the Lychnitis Palus (Lake Okhrida). As a general name it occurs first in the Byzantine writings of the eleventh century under the two forms Ἀλβανοί and Ἀρβανίται,[2]

[1] That is, Ἤπειρος, or "Mainland," so called no doubt originally by the Greeks of the adjacent island of Korkyra (Corfu)

[2] Kedrenus, Skylitzes, Anna Comnena. In Georg. Akropol. ("Annals," c. 68) occurs the expression τὸ τῶν Ἀρβανιτῶν ἔθνος. The forms Arberi or Arbernia for the land, and Arbereshi for the people are even still current amongst the Northern Albanians, and must at one time have been very general, for the various Albanian colonies settled in South Italy since the latter half of the fifteenth century even now call themselves Arbrèsh or Arberesh, and their language Arbrishte or Arberishte. In Greece also Ἀρβανιτία and Ἀρβανίτης are current as equivalents of Ἀλβανία and Ἀλβανός.

and from the latter seems to have been formed, 3, *Arnaut*, the general Turkish designation, though more strictly applicable to the Muhammadan Albanians. Thus Arnaut, Albanian, and Shkipetar, all traceable to roots meaning rock, height, would be practically synonomous, and aptly descriptive of an essentially "highland" race.

VI. Three Main Ethnical Divisions.—1. *Gheg* (Gepides) in Upper Albania, as far south as River Shkumbi, and penetrating eastwards across the Morava Valley nearly to Sophia, with detached enclaves in Servia, but on the other hand partly Slavonised on the Montenegrin frontier. Elsewhere the Ghegs are taken as the purest representatives of the old Illyrian stock. This word, the origin of which is unknown, was a term of contempt originally applied to them by their southern kinsmen. It has thus come into general use, although never employed by the people themselves, who use either the collective designation Shkipetar or the particular name of their tribe. 2. *Toshk* or *Tosk* (Toskides) in Central and Lower Albania, wherever not Hellenised. Originally confined to the Toskides proper of Toskeria, a small district on the right bank of the Lower Voyussa north-west of Topedelen, this word has also gradually acquired general currency, and so far differs from the corresponding Gheg that it is accepted and used by the people themselves, at least throughout the whole of the Voyussa basin. 3. The *Epirots* of the Vilayet Yanina from the remotest times largely intermingled with the Dorian Greeks, and now almost completely Hellenised. The term is of course rather geographical than ethnical, but very convenient in view of the political changes now pending in this district. In connection with these changes it will be useful to note that the Pindus range between Epirus and Thessaly is occupied by the Kutzo-Vlachs (the Kara-Guni or "Black Capots" of the Turks), with decided Hellenic proclivities, religious, political, and social, though still speaking a corrupt Rumanian (neo-Latin) tongue. Even in Epirus the Toshk itself, wherever still spoken, is largely mixed with Greek elements, and most of the Toshks themselves are here bilingual, speaking Greek and their mother tongue indifferently, while in Yanina, capital of the vilayet, Greek has long been supreme. Consequently the contemplated transfer of this territory to Greece, with which it has been uninterruptedly associated from prehistoric times,[1] cannot seriously affect the integrity of the Albanian race or do any undue violence to their legitimate national aspirations.

VII. Three Religions: 1. *Muhammadan* everywhere, but rather more general in the south than the north; 2. *Orthodox Greek*, almost exclusively in the south; 3. *Roman Catholic*, of Latin rite, almost exclusively in the north. From this it follows that the Ghegs are partly Moslem, partly Roman Catholic; the Toshks partly Moslem, and partly Orthodox Greek; the respective numbers being as under, as far as any such estimates can at all be depended upon in Turkey:—

	Moslem.	Orthodox Greek.	Catholic (Latin).	Total.
Ghegs ...	400,000 ...	50,000 ...	150,000 ...	600,000
Toshks ...	600,000 ...	200,000 ...	— ...	800,000

The diffusion of Muhammadanism no more implies the presence of Tûrki elements in Albania than it does in Herzegovinia or amongst the Bulgarian Pomaks of the Rhodope Mountains. Like causes have produced like results in all these places, and in Albania, when resistance ceased with the death of George Castriota, most of the influential and better classes adopted Islam, while the peasantry, who never had much to lose or gain either way, remained christian. We sometimes hear it said that religion is a racial test in Turkey, but from this it is evident that the statement can be true only in a negative sense. It is safe to say that here no Christians are of Tûrki stock; but the converse is very far from being the case, for we see from this table that in Albania alone there are no less than 1,000,000 Muhammadans who are not of Tûrki, but of Illyrian stock, apart always from a few Osmanli officials and others in the large towns.

Tribes.—It is not a little remarkable that the country which might almost be regarded as the cradle of European civilisation has itself remained nearly stationary since the rude Dorians issued forth from the mountains of Epirus to the conquest of Peloponnesus. Of all the western Aryans the Albanians alone have remained in a semi-pastoral state, and retained the primitive tribal organisation. Both branches of the race, but especially the Ghegs, are still divided into a considerable number of *phis* or *phar*,[1] that is, clans or septs, some of which, such as the Suliots in the south, and the Mirdites in the north, have acquired historic renown. George Castriota, the Scanderbeg, or "Alexander the Great" of the Turks, who almost single-handed for thirty years stemmed the torrent of Osmanli conquest, was Prince of the Mirdites, and the astounding valour and self-devotion of the Suliots form one of the most stirring episodes in the Græco-Turkish wars during the early part of the present century. Recently also such tribal names as those of the Klementi, Hotti, Dukazin and others have been heard of in connection with the present political troubles on the Montenegrin and Albanian frontiers. As such troubles are likely to be of a protracted character, pending the definite settlement of the new northern and southern frontier lines, the readers of Nature will probably be glad to have in the annexed table a complete classification of all the Albanian tribes:—

Ghegs.	Mirdites:—	Dukazin; Dibri; Mats or Matia; Oroshi Fandi; Kushneni, Spachi; Kuchi
	Pulati:—	Giovagni; Planti; Kiri; Summa; Toplana; Dushmani; Shalla; Shoshi
	Other semi-independent tribes.	Klementi; Hotti; Shrelli; Kastrati Rechiluho; Rioli; Posripa; Kopliki Grica Gruemir; Busagwit; Grudda; Trepchi
Toshks.		Toshks proper of Toskeria; Yapides or Liapes; Kheimariots; Khamides or Khumis Tyames; Suliots

Of all the tribal associations by far the most important are the Mirdites, who, although numbering scarcely over 20,000 altogether, form a powerful political factor in the country. They constitute a Roman Catholic oligarchy, whose chief town is Orosh, where resides their prince or chief. The confederacy is fully recognised by the Porte, to which it is tributary. Amongst them has long been prevalent the custom of marrying none but Turkish, or rather Muhammadan, women, carried off from the plains and baptised in the mountains. Their territory lies chiefly south of the Drin, and with the Pulati ("Men of the Woods"), Klementi, Hotti, and other highland tribes between the head streams of that river and Lake Skutari, they are often collectively called Malliesor or "Black Mountaineers."[2] But they must not on that account be confounded with the neighbouring Montenegrins, as some writers have recently done.[3]

Of the Toshk tribes the most influential are the Toshks proper on both banks of the Lower Voyussa; the Yapides or Yagys, who are the Lapides, Liapes, or Lapes of the Greeks, on the Akrokeraunian coast range as far south

[1] Here were the famous Oracle of Dodona and the no less famous rivers Acheron and Cocytus, which play such a conspicuous part in Greek mythology, and here was one of the early seats of the Dorians before they migrated southwards.

[1] Terms probably referable to the same Aryan roots as the Greek φῖτυ, implying blood relationship, and φρατρία, a wider tribal signification.

[2] From *mal*, mountain, and *sy*, black.

[3] F. Bianconi ("Ethnographie et Statisque de la Turquie d'Europe," Paris, 1877), speaking of the Kuchi, Klementi, Pulati, and Mati, says (p. 45) that "toutes ces races sont Slaves." But Ritter zur Helle von Samo ("Die Völker des osmanischen Reiches," Vienna, 1877), with his usual accuracy, includes them amongst the independent Albanian tribes of the Vilayet of Skutari. So also E. Reclus (I. p. 188) and Vivien de Saint-Martin (Art. Albanie, p. 50):—"Leurs tribus les plus notables sont au nord du Drin inférieur, entre les confluences des deux branches supérieures du fleuve et le lac de Scutari les *Klementi*, les *Hoti*, les *Kastrati*, et les *Poulati*, ou gens des forêts."

as the River Pavia,[1] and the Khamids or Khamis between the Pavia and Kalama Rivers over against Corfu. Many of the Khamids, however, have already been Hellenised, and the rest form detached communities everywhere surrounded by Greek-speaking populations, as correctly indicated on the ethnological map of European Turkey and Greece recently published by Stanford of Charing Cross.

Including the Albanian colonies since the fifteenth and sixteenth centuries settled in South Italy and Sicily, and many scattered Toshk settlements in the Morea, Attica, Eubœa, and the Archipelago, the whole race numbers at present considerably over a million and a half, as under:—

Upper Albania (Ghegs)	700,000
Central and Lower Albania (Tosks)	680,000
South Italy and Sicily	180,000
Greece and Archipelago	90,000
	1,650,000

LANGUAGE.—The broad distinction between the northern and southern branches of the race—Illyrians or Ghegs, and Epirots or Toshks—dates from the earliest historic records, and was clearly recognised by antiquity. The parting line between the two was much the same then as now, being fairly indicated by the famous Roman road, the Via Egnatia, running from Dyrrachium (Durazzo), on the Adriatic, through Okhrida and Bitolia (Monastir), to Thessalonica (Saloniki), on the Ægean. North of this great highway dwelt the Illyrians, Dardanians, and Pæonians, all closely allied in speech, south of it the Epirots and Southern Macedonians, also represented as originally of kindred speech and like customs, though both were later on largely Hellenised.[2] The difference between the northern and southern dialects still persists in Albania, where alone the Thrako-Illyrian language survives, the Gheg and Toshk standing in much the same relation to each other as High to Low German, or even to Danish. Hence the extreme northern and southern tribes are almost mutually unintelligible, although the the Toshks and Ghegs of the border districts (Ergent and Shkumbi valleys) are able to converse together. The Italo-Albanian Demetrius Kamardas accordingly takes the speech current in this central tract as the common "Illirio-Epirotic" standard.[3]

The linguistic affinities of Albania were long a source of great trouble to philologists, and its claims to membership with the Aryan family were only finally established beyond dispute by J. G. von Hahn.[4] But its position within the family itself can scarcely be said to have yet been satisfactorily determined. Bopp[5] compared it, after his usual method, chiefly with Sanskrit, while others have regarded it as simply an archaic or even a corrupt variety of Greek.[6] The truth would seem to lie between these extremes, and a more exhaustive study of the subject will probably show that in Albanian we have the only surviving link between the Asiatic and Græco-Italic branches of the Aryan family. An analysis of the southern dialect shows that of its roots about one-third are common to Æolic Greek, one-third to Italic, Keltic, Teutonic, and Slavonic, the rest consisting of an unknown element assumed to represent the speech of the ancient Thrako-Illyrians. The Italic, Keltic, Teutonic, and Slavonic words may be referred partly to their common Aryan inheritance, partly to contact possibly in prehistoric, certainly in historic times—the Keltic invasion third century B.C.; Gothic irruption under Alaric; Roman rule of five centuries; Serb occupation of Upper Albania to the Drin from 640 to 1360 A.D.; Bulgarian occupation of the central districts till 1019.

But what has been called the Æolic Greek element seems rather to date from a common pre-Hellenic period, for it often presents a more primitive phonetic system, and more archaic grammatical and lexical forms than the oldest Greek extant—forms which cannot be derived from Greek, but which are intermediate links between Hellenic and Asiatic Aryan. Thus the Albanian *bolnesa* = *will* (noun) explains the Greek *βουλομαι* for *βολνομαι*, connecting it with the Sanskrit *varnamai*. Alb. *dera* = *door*, stands between Gr. *θύρα* and Sans. *dvâra*; Alb. neër or niër = *man* between Gr. *ἀ-νήρ* and Sans. *nar*. Here the organic *a* has become *e* both in Alb. and Gr., but Alb. has not taken the prosthetic *α*, a sufficient proof that it does not derive from, but belongs to an older period than, Greek. Grammatical forms point in the same direction. Thus the Alb. genitive in *tye*, as in *atiye* = *of him*, answers to the Sans. *sia*, *sya*, and to the old Gr. *εῖο*, *εο*, *οῖο* = *ου*, as in *ἐμεῖο*, *ἐμέο*, *ἐμοῖο*, *ἐμου*. The numerals, often so instructive in comparisons of this sort, place the matter in a still clearer light. Thus Alb. *nyê*, *nya* = *one* = Gr. *εἷs* for *ἕν-s*, neutral *ἓν*; *κατтερ* = *four*, has the organic *k*, which in Gr. becomes *t* (*τέτταρ-ες*), Sans. *katvar*, *katur*, Lat. *quatuor*. Compare also Alb. *gvash-te* = *six* with the Sans. *shash* and Gr. *ἕξ*, where the Alb. *g* forms the intermediate stage between the original sibilant and the Gr. rough breathing. In *shetta-te* = *seven* Alb. retains the sibilant, here standing on the same level as Sans. *saptan*, as compared with Gr. *ἑπτά* for *σεπτά*.

In other instances Albanian shows great corruption and phonetic decay, as might be expected in a rude, uncultivated tongue never reduced to writing till quite recently. But the corruption and decay always proceed on different lines from those followed by Greek in its evolution. Thus Alb. *nēn-te* (Skutari dialect *nān*) and Gr. *ἐννέα* = nine, have both lost the digamma preserved in the Sans. *navan*, from which each flows in independent channels: Alb. *nefan*, *nean*, *nēn*, *nān*; Gr. *ἀννεϝαν*, *ἀννεϝα*, *ἀννέα*, *ἐννέα*, here prosthetic *α* causing reduplication and loss of final *ν*.

The general tendency of Albanian, as of French, is towards short and contracted forms, the suppression of middle and weakening of final vowels to *e* mute or *eu*. This, combined with a somewhat barbarous system of orthography, half Greek, half Latin, which has here been replaced by a simple phonetic system, gives the language a decidedly rough and uncouth look, though it is by no means deficient in harmony, and what Kamardas finely calls a certain Hellenic "aura," so that "at times we fancy we are listening to Greek instead of Albanian utterances.)[1]

The determination of the true position of Albanian is of such importance in the history of Aryan speech that the reader will probably excuse this somewhat dry excursus.

TYPE.—From many of the foregoing indications it is obvious that the Albanians can by no means be regarded as a pure race. In popular works of travel or fiction a certain halo of romance is thrown over the people, who are represented as endowed with almost classic symmetry of form and beauty. This is to some extent true in the south, where intermixture with the kindred Hellenes could scarcely be otherwise than beneficial, and even in

[1] Here was Ptolemy's Albanopolis, and here is a maritime canton still called Arberia or Arberi, and in Gheg Arberia, that is, Albania. The interchange of *r* and *l* is a prevailing feature in Albanian, as in French, Chinese, Polynesian, and so many other tongues. The peasantry about Frascati and elsewhere in the Campagna call the English *Ingresi* for *Inglesi*.

[2] Thus Strabo (vii.): "Leaving Epidamnus and Apollonia (Durazzo and Polini) to follow the Via Egnatia, we have on our right the peoples of Epirus, bordering on the Sicilian Sea as far as the Gulf of Ambracia, and on our left the Illyrian highlands and the peoples of that region as far as Macedonia and the Pæonians."

[3] "Saggio di Grammatologia comparata sulla Lingua Albanese," Leghorn, 1865, p. 19.

[4] In his classical work "Albanesische Studien," Jena, 1854.

[5] "Ueber das Albanesische," Berlin, 1855.

[6] Amongst others the anonymous author of the introductory remarks to Stanford's Ethnological Map, who (p. 8) speaks of the Albanians as "Greeks in their original and elementary condition," a fact "now clearly established . . . by the study of the Albanian dialect, which modern comparative philology has shown to be but *another form of the Hellenic language*."

[1] "Una certa aura, per così dire, d'ellenismo, che ti fa talora credere d' udire parole greche invece di albanesi." *Op. cit.*, p. 19.

the extreme north, where the elements here absorbed belonged to some of the best Slav blood—Serbs and Montenegrins. But the plain and often even repulsive features met with in some of the central districts would seem to point at fusion with the Ugrian or Volga Finn Bulgarians, whose headquarters were at Okhrida, and who at that time (8th and 9th centuries) had not yet been Slavonised. Nevertheless, the Albanians are on the whole a fine and even a handsome race, with long head, oval face, long thin nose, rather high cheek bones, small eyes, generally grey or blue, hair often fair or light brown, long neck, broad chest, slim and upright figures. But descriptions of course vary with the experiences of the observer. Thus while Pouqueville speaks rather of black eyes, others describe the Toshks as essentially a blue-eyed and light-haired race. In general the purest type is found in the district between the Shkumbi and Voyussa, where Kamardas says that the language also is spoken in the greatest purity. North and south of this district both people and language are more or less intermingled with Slav and Hellenic elements respectively.

A. H. KEANE

REPORT OF THE BRITISH MUSEUM

THE Parliamentary Report of the Trustees of the British Museum, which has been lately issued, tells us that during the past year much progress has been made in arrangements for removal of the natural history collections, and in preparations for their reception in the new buildings designed for them at South Kensington. New cases and fittings have been provided and erected for the departments of botany and mineralogy, and in part for that of geology; and the transference of these three collections to the new museum will probably be effected in the course of the present year. The galleries vacated by these collections will be at once made use of for the exhibition of objects of archæological interest which have been accumulating for many years, and from want of space have been stored away in imperfectly-lighted rooms in the basement of the British Museum.

The whole of the zoological and geological portions of the India Museum at South Kensington, together with the friezes from the Amravati Tope and other remains of ancient sculpture, have been made over by the Secretary of State and Council of India to the Trustees of the British Museum. The sculpture will be exhibited in the Museum; the zoological and other collections have been removed to the New Natural History Museum at South Kensington.

Turning to Prof. Owen's special report on the departments of natural history, we are told that part of the work during the past year has been that of the preparation of the collections for the pending transfer to South Kensington.

In the department of zoology Dr. Günther informs us that not less than 45,881 specimens have been added to the several parts of the collection; of this, however, more than half is attributable to the collection of exotic butterflies, bequeathed to the nation by the late William Chapman Hewitson. This is one of the most extensive and valuable collections of this group of animals that has ever been formed; it consists of 24,624 specimens referable to 5,795 species, many of which have been described by the testator in his "Exotic Butterflies," "Diurnal Lepidoptera," and other works. The collection is in a perfect state of arrangement and preservation, and by Mr. Hewitson's direction a catalogue of its contents has been prepared and printed at the expense of his estate. The testator attached to this bequest the condition that the collection should be called the "Hewitson Collection," and should be kept in good order, preservation, and condition, and in the same cabinets, and in the same order and arrangement, and under the same nomenclature as they should be at the time of his decease, until the expiration of twenty-one years from that time.

Another important addition to the national collection of insects made during the last parliamentary year was the Wollaston collection of St. Helena Lepidoptera, consisting of 364 specimens, and including types of thirty-eight species, collected and described by Mrs. Vernon Wollaston. This must be regarded as one of the most important acquisitions of last year, as the accurate and perfect knowledge of the fauna and flora of so isolated a locality as St. Helena at a given period will enable future investigators to determine exactly the changes which are taking place in oceanic islands, not only with regard to the composition of their fauna and flora, but also with regard to the specific characters of the animals and plants imported into them.

Four additions have been made to the well-known series of zoological catalogues in 1879, namely, the fourth volume of Mr. Sharpe's "Catalogue of Birds"; an octavo volume by Mr. C. O. Waterhouse, containing descriptions of typical specimens of coleoptera, illustrated by coloured plates; a volume containing descriptions of a number of new species of hymenoptera by the late Mr. Frederick Smith, which the lamented author left nearly ready for publication at the time of his death; and the third volume of Mr. Butler's "Illustrations of Typical Specimens of *Lepidoptera heterocera*."

Mr. Waterhouse's report on the Geological Department and Mr. Story Maskelyne's on that of Mineralogy succeed that of Dr. Günther, but we observe nothing of very special interest contained in them. Mr. Carruthers' report on Botany records an important addition to that department in the shape of the extensive herbarium of the late John Miers, F.R.S., &c., the distinguished botanist, which he bequeathed to the Trustees. It contains the types of the species described in his numerous systematic works and memoirs, as far as they were in his own possession, together with an extensive series of South American plants from various collectors, and many valuable collections from other regions of the world. Besides the plants Mr. John W. Miers has presented to the department the large series of original drawings made by his father from the living plants in South America and from dissections of plants in later years.

MARCEL DEPREZ'S GALVANOMETER FOR STRONG CURRENTS

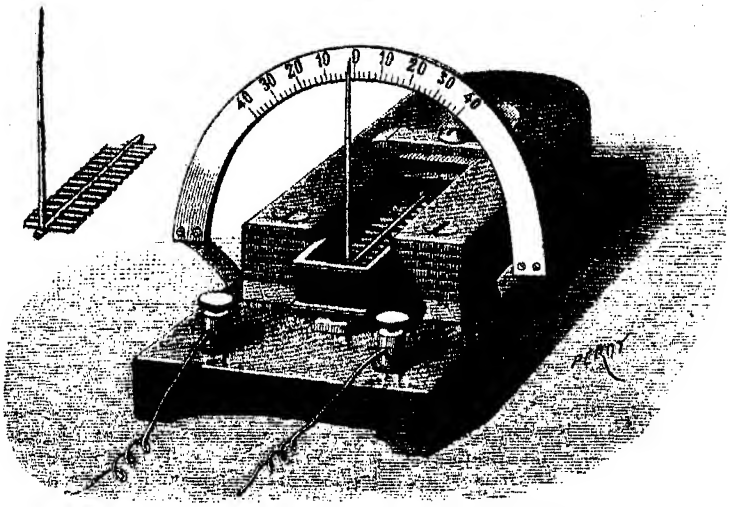
PRACTICAL electricians have laboured up to the present time under a considerable difficulty in attempting to measure the strength of very powerful electric currents, such as are, for example, employed in the production of the electric light. There has been no simple instrument suited to the rapid direct measurement of the strength of such currents, much less one that would measure any fluctuations of short duration. Ordinary galvanometers have not been equal to the task, being adapted for a different class of work, usually of too high a resistance to be safely introduced into the circuit, and in general too leisurely in their movements to afford indications of any rapid fluctuations.

Although the current furnished by a good dynamo-electric machine, such as those of Gramme, Siemens and Brush, may for most practical purposes be considered both continuous and uniform, the construction of these instruments could hardly leave any doubt on *a priori* grounds that the current really consists of a number of successive impulses, which, although they may, as it were, run into one another and yield a continuous current, yet cause the strength of the current to be continually increasing and diminishing in rapid alternations; and indeed the telephone shows clearly that this is the case, for a low humming sound is heard in that instrument when its

terminals are joined to the two ends of an insulated wire, part of the length of which is laid parallel and near to the conducting-wire of the dynamo-electric machine. M. Deprez's new galvanometer shows by the most direct evidence that this is the case, for when inserted in the circuit of any dynamo-electric machine its needle is observed to be in incessant vibration.

The only instrument constructed previously to that we are about to describe, suitable for measuring strong currents, was the tangent galvanometer of Dr. Obach, the essential feature in which consisted in the conducting-ring being made movable about a horizontal diameter, and therefore capable of being adjusted by inclining it at a greater or less obliquity to any degree of sensitiveness between its maximum and zero, the horizontal component of the magnetic force of the current circulating in it being zero when the ring was laid over into a horizontal plane.

M. Deprez's galvanometer is, however, a much more handy instrument, its indications are almost instantaneous, and the deflections with very strong currents are not unreasonably great. To secure this end it has been necessary to make the needle of the instrument very light, and at the same time to give it a very great directive force by placing it in an artificial "field" of very great intensity. The needle consists of twelve or fifteen little pieces of soft iron wire set side by side transversely



Marcel Deprez's Galvanometer for very strong currents.

upon an axis of brass which is supported between two pivots. The axis carries also a light hand or index of straw or aluminium fixed at right angles to the little iron needles. This compound needle is placed between the limbs of a powerful permanent magnet made of separately magnetised laminæ superposed upon one another (as suggested by Scoresby and Jamin), and is thereby powerfully magnetised and directed into the horizontal plane. The coils of conducting wire are carried round the needle by being wound upon a light rectangular frame which surrounds the needle, but lies within the limbs of the permanent magnet. When a current passes the needle jumps almost instantaneously to its position of equilibrium, its oscillations being of extremely short duration. M. Deprez has also tried needles made up of several superposed layers of the thin sheet iron used in telephones, but the form shown in the figure is, on the whole, the most satisfactory in practical operation. One advantage possessed by the instrument is that it is independent of gravity and of the magnetism of the earth, and can therefore be used anywhere in any position. It will, therefore, be found to be a very convenient instrument for electrical engineers, but as its readings are not capable of being translated into values representing current-strengths by any simple trigonometrical function, sines or tangents, it would require to be graduated empirically by a process similar to the method of "calibration" adopted for ordinary galvanometers by Melloni, before it could be regarded as more than a convenient galvanoscope.

PROF. W. H. MILLER

It is only just to the memory of a man conspicuous within the circle of a not very large scientific class that more than a passing word should be spoken over his grave before the grass has grown on it.

William Hallows Miller, whose life began with the century, has lived far enough into it to experience what is a happy fate for a scientific man; he has seen the chief work of his life bear fruit; has seen the system he introduced holding its place in the face of other systems, and recognised more and more as a permanent addition to the agencies with which man may grapple with the problems that nature presents to him; he has seen it developed, but not superseded.

Crystallography was Miller's science. It had taken its first shape in the hands of Haüy in the decade of years before he was born, and in those of Weiss, of Mohs, and especially of Franz Ernst Neumann and of Grassmann, it had been receiving development during the years of Miller's growth and manhood.

The chair of mineralogy at Cambridge was filled previously to 1832 by Dr. Whewell, and a well-known memoir on the geometrical treatment of crystal forms which Dr. Whewell contributed to the *Transactions* of the Cambridge Philosophical Society gave an impetus to the study of crystallography in England which launched Miller on his career. For, taking this memoir and Neumann's treatise of 1823 (*Beiträge zur Krystallonomie*) as his starting-point, Miller, who was a pupil of Whewell's, proceeded to develop a system of crystallography which was not published till 1838, but which was the most important work of his life.

Dr. Whewell had already for some time recognised in his pupil the ability and accuracy that marked him out for the career he afterwards pursued, and in 1832 the

historian of the inductive sciences resigned his chair and used his disinterested influence to obtain the appointment of Miller as his successor.

Previously to this, in 1825, Miller had taken his degree as a fifth wrangler, and he obtained some reputation as a tutor. In 1831 he published an elementary treatise on hydrostatics, and in 1835 one on hydrodynamics. They bore the mark of the same concise and precise treatment, and excision of all that was merely explanatory, which gave afterwards its character to his treatise on Crystallography, and probably deterred the ordinary student from that subject far more than any real difficulties inherent in the science.

Already in 1829 he had published a crystallographic notice of the forms of ammonium carbonate, followed in 1830 by two other memoirs, and thenceforward notices from time to time emanated from his pen on crystallography and on optical and physical subjects.

Miller was thirty when he succeeded to the chair, which he occupied forty-eight years.

The system of Weiss indicated the position of a face on a crystal by expressing its intercepts on a system of axes in the form of integer multiples of the intercepts (parameters) of some other selected crystal-face on the same axes.

The system of Miller represented the face by a symbol composed of three numerals, or indices, which are the denominators of three fractions with unity for their numerator and in the ratio of the multiples of the parameters; and he asserted the principle that his axes must be parallel to possible edges of the crystal.

The elegant way in which this mode of representing a face lent itself to yielding expressions for the relations between faces belonging to a zone (*i.e.* faces that would intersect in edges parallel to the same line) gave it superiority over previous methods, due to its bringing the symbols of the crystallographer into a form similar to that employed in algebraic geometry. But though expressions were given for the relations connecting four crystal planes in a zone, the principle lurking in them of the rationality of the anharmonic ratios of four such planes was not recognised, or at least was not announced as such, by Miller till 1857, nor were the further results deducible from this principle ever propounded by him. It was by a pupil of Axel Gadolin's and by V. von Lang independently that the limitations imposed by this principle on the varieties of crystal symmetry were first set forth; but Bravais had already deduced the necessity for these limitations by a parallel method of reasoning founded on the idea of what may be termed a net-pile of the centres of mass (*Raumgitter*), that is to say, a parallepipedal system of arrangement of molecules. But Miller's work consisted in working out into a beautiful system the indicial method of notation and calculation in crystallography, and obtaining expressions adapted for logarithmic computation by processes of great elegance and simplicity. The faces of a crystal he followed Neumann, Whewell, and Grassmann in representing by normals to the faces, which are conceived as all passing through a common point; and this point is taken as the centre of an imaginary sphere, the sphere of projection. The points, or poles, in which the sphere is met by these normals, and which therefore give the relative directions in space of the faces of the crystal, can have their positions on the sphere determined by the methods of spherical trigonometry. Moreover a great circle (zone circle) traversing the poles of any two faces will traverse all the poles corresponding to faces in a zone with them.

By the aid of the stereographic projection, which Miller also adopted from Neumann, he was able at once to project any of these great circles on a sheet of paper with a ruler and compasses, and for the purposes of the crystallographer elaborate edge-drawings of crystals become of comparatively little importance. Miller's system then gave expressions for working all the problems that a crystal can present, and it gave them in a form that appealed at once to the sense of symmetry and appropriateness of the mathematician.

His book at length became recognised by physicists and by the higher school of crystallography as one to supersede what had gone before it, as is evidenced by its having been translated into French by no less a man than Senarmont, into German by Grailich, who added a valuable chapter to it on crystallographic physics, and into Italian by Quintino Sella, and by its being now almost universally employed in crystallographic physics.

The future development of crystallography, there can be little doubt, will follow on the lines laid down by Miller, whatever may be the direction that development will take; and in the cause of higher scientific education, it is much to be regretted that in a National School of Mining and Mineralogy like that established in Jermyn Street the elaborate and relatively clumsy system of notation introduced by Naumann should still be retained, to the exclusion of an incomparably more comprehensive and reasonable system which has at least the advantage not only of being English in its completed form, but of having been originated by mathematicians so eminent as Neumann, Grassmann, Whewell, and Miller. For it is to be borne in mind that the (so-called) system of Naumann, apart from his long superseded geometrical treatise, is nothing but a system of notation for the general forms, and not for the particular faces of a crystal, and becomes more complicated in proportion as the symmetry of the crystal is more simple, while it is entirely useless in the methods of computation, its symbols being actually converted by the modern crystallographer who uses them into the Millerian symbols on every occasion when he wishes to deduce relations between faces and the zones to which they belong.

Besides his memoirs describing the results of crystallographic measurement and certain tracts such as that on the gnomonic projection and on the crystallographic method of Grassmann, Miller published in 1863 a tract on crystallography which was, in fact, a second edition of his original treatise.

In 1852 he published his great work, for it was all his own, on Mineralogy, modestly entitled a new edition of the "Elementary Introduction to Mineralogy, by the late William Phillips," by H. J. Brooke and W. H. Miller. The publication of this severe little volume was an epoch in the science it illustrated. It contained a mass of results obtained by Miller with all his accuracy and all his patience through many years, and tabulated in his usual concise manner. It may be said to have fired the zeal and directed the general form of the greater but still uncompleted work of his friend Des Cloizeaux. It is a monument to Miller's name, though he almost expunged that name from it. Like other work of his it may be merged in the larger works of newer men, but it will not be superseded, and will always have to be referred to.

One of the great works of Miller's life was the restoration of the standards lost in the fire which destroyed the Houses of Parliament. The microscopic accuracy of his mind here had a congenial task; and another conspicuous quality of that mind had to be brought into play in devising the elaborate precautions to be taken in order that the balances and apparatus employed might be sufficiently sensitive, and at the same time absolutely accurate when considerable weights were under determination. Indeed there was no faculty for which Miller was more remarkable than this of devising readily the most simple means of making an experiment and the apparatus needed for it.

His room at the Cambridge Museum was a storehouse of such simple and almost improvised furniture, embracing forms of apparatus needed by a crystallographer and observer using optical instruments: a little heliotrope suggested to him by a crack in the window of a railway

carriage; a clock of wondrous simplicity and accuracy, the motive power of which was a drop of water, a fresh drop always waiting ready to be picked up and to give its impulse to the returning arm of the escapement; a goniometer, consisting solely of a block of wood with a straight edge, and an upright wire with its end bent round so as to carry a cork with a second wire on which the crystal was fastened, and by which it was adjusted for measurement on Wollaston's method, the angle between two positions of the straight edge being found by the aid of a pair of compasses and determined by a continued fraction. These are a few only of the marvels of ingenuity which every one admitted to that interesting room will remember; and there were implements of observation fashioned out of the simplest materials—deal, cork, glass tube, wire—by the hand of their inventor, rough to look at, but exact in their performance. Nor was there any man who better appreciated the elaborate mechanism of an important instrument; no one, for instance, who could make an afternoon at the Greenwich Observatory more interesting and suggestive alike to the instructed student and to the uninformed visitor.

Such was the work of Miller. Personally he was quiet, unobtrusive, but observant; retiring, almost shy, in his manner, but in the highest degree genial and full of cordiality when this curtain of instinctive restraint was drawn aside and you met the man himself face to face.

He was a traveller. Impelled by his old master Whewell to the study of German as necessary to a mineralogist, he spent many a long vacation in the German and Tyrolese haunts of the mineralogist, and lost no opportunity of exchanging speech and therewith winning the esteem of the masters of his science on the Continent. Most of those contemporaries he survived. Mitscherlich, Gauss (who paid him the just tribute of complimenting him with having "exactly hit the nail on the head" in his Crystallography), Dove, Gustav Rose, Haidinger, Breithaupt, Wöhler, Sartorius von Waltershausen—names many of them but yesterday of living workers, were those of silent men before Miller's grave was closed, but they and Miller had in life been united by esteem and regard, and in some cases by warm friendship.

Of the travels which thus brought friendships and new scenes home to him, and in which he acquired valuable additions to the mineral collection at Cambridge, he had other pleasant records in the sketch-books which his constant companion, Mrs. Miller, filled as they journeyed.

Those who know the broad strath of the Towey above Llandilo in Carmarthenshire will remember, near its head, in the neighbourhood of Llandovery, a pretty gentleman's seat named Velindra. This was Miller's birthplace. Here his father, Captain Francis Miller, had settled towards the close of the last century, after fighting as an officer in the English army throughout the American War of Independence, and after losing a good estate which he possessed in the Boston Government, and which he never recovered. He too came of a fighting family, and doubtless something of the independence, the reserve and gentlemanly courtesy of the crystallographer came to him through this inheritance.

The valuable collection of minerals at Cambridge was largely the fruit of Prof. Miller's long-vacation rambles. The addition to it of the collection of Mr. Brooke, presented by his son, the late Mr. Charles Brooke, was an appropriate gift, considering the illustrations Miller had so copiously drawn from that collection for the important treatise on Mineralogy, to which he modestly gave the title of an edition of Phillips' "Mineralogy," by Mr. Brooke and himself: the real authorship of all that made the book invaluable to the true mineralogist being his whose name stood last, though for ever greatest, on the title page.

Some of his later years were devoted to arranging in the New Museum at Cambridge the collection he had done so much to form. He did not live to make a catalogue of it, though Mr. Lewis, who during Prof. Miller's illness was intrusted with the duty of acting for him, has commenced the laborious work of a register, as a preliminary to a catalogue.

There have been rumours that a change would be made in the character of the chair before the appointment of a successor to Prof. Miller. Considering that but for the two mineralogical chairs at the two great universities of England the study of crystallography otherwise than as an almost childish adjunct to popular lectures on mineralogy would have been extinguished in England, it may be worth while to urge that the significance of crystallographic structure as a key to great physical problems, and probably too, when the chemists have awakened to the fact, as a key to some of the newest problems in chemistry, gives to crystallography a very considerable claim for recognition among the subjects taught in the university that produced the greatest crystallographer of our time. N. STOREY MASKELYNE

PAUL BROCA

We regret extremely to have to announce the death of this distinguished physician and anthropologist, which took place suddenly at Paris on Thursday last. He had attended a meeting of the Senate, of which he had lately been elected a member, and died during the night in consequence of the rupture of an aneurism. He was fifty-six years of age, born at St. Foy, in the Gironde, educated for the medical profession, and became Professor of Surgical Pathology at Paris. He soon acquired a high reputation by his researches in cerebral pathology, and continued to devote himself with great zeal to hospital work and clinical teaching to the last; but it is chiefly in consequence of his having taken up the subject of anthropology that he has obtained a world-wide fame, and occupied a position which it will indeed be difficult to fill up.

Twenty years ago the science of physical or anatomical anthropology was in its infancy, and all investigations were at variance even as to the methods to be pursued in its cultivation. Broca devoted many years of unceasing activity in endeavouring to define, systematise, and perfect these methods. The thoroughness and energy with which he threw himself into any research which he undertook were marvellous, and only equalled by the clearness and facility of expression with which he communicated his results to others. His series of essays on various subjects connected with craniometry, published in successive numbers of the *Mémoires* of the Société d'Anthropologie of Paris, and the *Revue* which he founded, and his "Instructions craniologiques et craniométriques," with the introduction of numerous neat and happily chosen terms for descriptive processes, have made an immense advance in the progress of the science.

Happily Broca's perfect simplicity and amiability of character, his pure love of science for its own sake, and his readiness to help those engaged in pursuits similar to his own, have inspired with enthusiasm most of those who came in contact with him; and he has created at Paris a school which it is to be hoped will carry on the work which he inaugurated. We may take occasion to notice his scientific work in greater detail in an early number.

THE UNITED STATES WEATHER MAPS, SEPTEMBER, 1878

In the description of the United States Weather Maps for August, 1878, attention was drawn to the fact (vol. xxii. p. 36) that in that month atmospheric pressure was under the normal over a broad belt going halfway round the globe, extending from the Rocky Mountains across the United States, the Atlantic, Europe, and thence into Asia as far as the valley of the Lena, and the

bearing of this abnormal distribution of the pressure on the temperature, winds, and rainfall of this large and important part of the globe was adverted to. In the September following, the U.S. Weather Map for which appears with this notice, great and radical changes in the distribution of pressure took place—such as a change from a large defect from the normal pressure to a large excess above it in the New England States, South Britain, Central Europe, South Africa, and New Zealand; and on the other hand, a change equally striking from a large excess above the normal to a large defect from it over the West India Islands, South Greenland, Iceland, North Britain, and the whole of Southern Asia from the Bay of Bengal to Japan. As it is still premature to speculate on the causes of these enormous changes in the distribution of the mass of the earth's atmosphere and the still more enormous forces called into play in effecting them, we must content ourselves with stating them a little more in detail, and drawing attention to some of the more immediate and striking climatic consequences which followed in their train.

In North America pressure fell most below the normal about Lake Winnipeg, and southwards over the region traversed by the upper tributaries of the Missouri and Platte Rivers. This region of low pressure was extended, though in a less pronounced form, to the south-east, deepening again, however, on approaching Florida, to 0·090 inch, the greatest depression below the normal in the Bahamas. Over the Gulf States and westward through Texas and California, pressure was above the average; and to the north-eastward of the region where pressure was low it rose gradually, till in the Gulf of St. Lawrence it stood at 0·133 inch in excess of the average.

This high pressure extended across the Atlantic, and thence overspread Ireland, England, the northern half of France, Germany, all Russia except the extreme south near the Black Sea, and on into Siberia as far as the valley of the Tobol. As already stated, the southern half of Africa and the whole of New Zealand had a pressure considerably above their normal, the excess in the northern island of New Zealand being about 0·150 inch.

To the north of the European belt of abnormally high pressure there was a widespread region of low pressure including South Greenland, Scotland, Denmark, and Scandinavia, the centre of greatest depression being 0·209 inch below the normal in the north-east of Iceland. On the other side of the European belt of high pressure lay a most extensive stretch of low pressure covering the Spanish peninsula and the rest of Southern Europe; the north of Africa, all Asia, except Siberia to westward of the Tobol River and a small patch including the Lower Amur, the East India Islands, and the whole of Australia. In this widespread region centres of still deeper depression were formed in Italy, the Upper Obi, Western India, Southern China, and the south-eastern division of Australia, the depressions below the normal pressures of these five regions being respectively 0·133 inch, 0·146 inch, 0·084 inch, 0·070 inch, and 0·136 inch. The sharpness with which the regions were marked off will be seen from the statements that in their relations to the normals pressures showed differences of a fall of 0·342 inch from Nova Scotia to Bernfiord in Iceland, 0·329 inch of a rise from Bernfiord to Cork, and 0·153 inch of a fall from Cork to Rome, and 0·290 inch of a rise from near Melbourne to Napier in New Zealand.

In the United States, temperature was under the average on the western side of the area of low pressure, the deficiency from long. 98° W. to the Rocky Mountains being from 1°·5 to 3°·0. This low temperature extended far to northward, the deficiency from the normal amounting to 4°·5 at York Factory, Hudson Bay. In the region of high pressure which overspread the New England States the rainfall was small, and temperature from 1°·5 to 3°·5 above the normal. On advancing, however, to the north-east temperature fell to near the average in Newfoundland, which lay just on the western outskirts of the great barometric depression which had its centre near the north-east of Iceland. Greenland was completely enveloped in the western division of this depression, and there it will be seen that winds were northerly and easterly, and temperature consequently fell to 4°·0 below the normal. On the other hand, Scotland occupied the south-eastern segment of the barometric depression, and there, consequently, winds were west-south-westerly; temperature was from 1°·0 to 2°·0 above the average; and the rainfall in the west of the country from 40 to 110 per cent. above the average; whereas near the east coast it was about, or rather slightly under, the average. Thus in Scotland the distribution of the rainfall of September was the reverse of what prevailed in August, the weather in the latter month being fine and dry in the west, but wet and backward in the east. These differences of weather were occasioned by the circumstance that in August the centre of greatest barometric depression was to the south-west of Ireland, thus resulting in rain-bringing easterly winds in Scotland with the distribution of the rainfall stated above; whereas in September the centre of the barometric depression was near Iceland, thus resulting in rain-bringing westerly winds in Scotland, and consequently unfavourable weather in the west, but favourable weather in the east for the ingathering of the harvest.

Temperature was about the average in England, slightly under it in France and Western Switzerland, but above the average over the whole of the rest of Europe, and eastward into Asia as far as the area of high pressure extended. The greatest excess of temperature over this extensive region occurred in the great plains of the Danube and the Dnieper, where it amounted to from 4°·0 to 5°·6. In Italy the excess was small, and in Sicily temperature even fell 1°·4 below the average, and this area of low temperature was continued to the north-west through France. Another breadth of low temperature, falling however nowhere lower than 2°·0 below the normal, extended from the Caspian Sea as far to the north-east as the head-waters of the Yenisei, in other words over the western side of the barometric depression which overspread this part of Siberia. To the eastward of the Yenisei temperature was above the average, but only slightly so, nowhere exceeding 2°·0.

The greatest barometric depression in Australia lay off the coast south of Melbourne, and in accordance therewith, keeping in view the law of the winds of the southern hemisphere, the prevailing winds were N.E. and N. at Gabo Island and Melbourne, and N.W. and W. at Sandhurst and Portland; in other words, with the distribution of pressure described, equatorial winds blew over this part of Australia, and the temperature rose at Wilson's Promontory to 3°·2 above the normal; and the winds being land winds, the rainfall, particularly at places in the interior, was considerably below the average. In New Zealand pressure was not only absolutely higher in the north than in the south, but also much higher relatively to the normals, and it was also higher in the west than in the east. Under this distribution of the pressure and the strong equatorial winds resulting therefrom, temperature rose above the normal over the whole of New Zealand, the excess being nearly 4°·0 at Dunedin, Christchurch, and Napier.

NOTES

It was scarcely to be expected that the debate last Friday in the House of Commons on Mr. Roundell's motion for the complete abolition of the clerical headships and fellowships at Oxford and Cambridge should have had any other ending than it had. The Government thought it scarcely fair to the University Com-

missioners to interfere with what is regarded as one of the points which they are bound to consider. At the same time it is believed that the Commissioners are favourable to the almost complete abolition of clerical tests, and if this is one result of their deliberations, it seems to us their appointment will not have been in vain. The memorial on the subject, with 800 signatures, presented to Mr. Gladstone, could scarcely be more influential. Among the names are those of Sir G. Jessel (Master of the Rolls), Sir Henry Thompson, Dr. Risdon Bennett (President of the Royal College of Physicians), Mr. Darwin, Prof. Huxley, Mr. A. R. Wallace, Dr. W. B. Carpenter, Dr. Abbott, numerous members of Parliament, the Presidents of the Congregational and Baptist Unions and the Dissenting Deputies, the professors of most of the Nonconformist colleges, and several hundred graduates of the Universities of Oxford, Cambridge, London, and Scotland. It seems clear that the days of this remnant of an age of intolerance are numbered, and that in the near future Oxford and Cambridge will be as untrammelled by antiquated restrictions as the London and Victoria Universities. The central institutions of these bodies have developed with a marvellous rapidity, one cause of which, we must believe, has been the perfect liberty of teaching. University College, as we intimated last week, feels urgently the necessity of more elbow-room, and yesterday the foundation of Victoria University was celebrated at Manchester, where Owens College, the nucleus of the University has developed quite as rapidly, at least, as her elder sister of London. When Oxford and Cambridge have been brought as much abreast of the age as the two younger institutions, an impulse will be given to higher education in this country, and an encouragement to research in all departments of learning and science, that in time will bring us on a level with Germany in respect of University education.

No more satisfactory token of the rapid progress of liberal and just ideas as to the proper functions of universities could be desired than the tone of the leading article in the *Times* of Tuesday in connection with the Victoria University ceremonies at Manchester. After giving a melancholy picture of the disastrous effects of the existing system at Oxford and Cambridge, both on crammers and crammed, the *Times* gives what is evidently its ideal picture of university life. "Let us imagine," the leader concludes, "a body of professors employed not in examining or in cramming, but in original research or original work of some sort, pushing forward the bounds of knowledge, adding new ideas to the possessions of the human mind, creating, in short, and not merely appropriating or aiding and testing the appropriations of other people. The stimulus of such work as this would be felt, we may be sure, by all who come in any sense within its range. The example would be contagious. Original workers will be in no want of pupils, whether they seek for them or not. When valuable ore is being dug there will always be some one with a due sense of its worth ready and eager to pick it up. It is for the promotion of such work as this that great funds and great institutions most properly exist. The professions and trades of the country have their own appointed rewards. The successful barrister or the successful merchant may or may not have been a university student. It is not in any case the chief duty of a university to assist him in the attainment of his rank, first to sharpen his tools for him and then to keep him in funds during the interval while he is waiting to use them. The professions and trades can hold their own very well without such adventitious help as this. Original work is not so directly remunerative; to the individual engaged upon it it may not be remunerative at all. It often bears fruit slowly, but it bears it abundantly in the end. It needs, therefore, and justifies the special encouragement which a university can most obviously provide. The Victoria University has its life before it. It can choose its own course. It may become a machine for turning out second and third-rate intelligences, a sort of procrustean bed, so constructed as to bring its sons as nearly as possible to the same intellectual stature and equally to forbid any of them from falling far short of it or from exceeding it. Or it may propose to itself another aim, and may seek principally to aid in the creation of knowledge rather than in its distribution, and even weighing out." We are pleased to find the views we have so long advocated finding acceptance in so influential a quarter, and we commend the article to the earnest consideration of the University Commissioners.

The second annual meeting of the Index Society was held on Friday last, the 9th inst., in the rooms of the Society of Arts, when His Excellency the American Minister, Mr. J. Russell Lowell, presided. The Report contained an account of the work already accomplished and of that which is in hand or can be put in hand when the list of subscriptions is enlarged. Many of the Indexes issued through the Society refer to literature and history matters, but science is not overlooked. A Handbook of the Literature of Botany, by Mr. Daydon Jackson, the secretary of the Linnean Society, is just ready for the press, and a companion volume for meteorology is proposed. Indexes of Logic and Anthropology also find a place in the list of schemes. Besides the formal business at the meeting, resolutions were passed for the appointment of committees to consider the best means of carrying out the following objects:—(1) The indexing of biographical collections, especially those contained in the *Gentleman's Magazine* and the *Annual Register*: (2) the indexing of Roman antiquities and remains in Great Britain; and (3) the opening of an office to contain the printed and MS. indexes.

We have already called attention to the fact that the friends of the late Prof. Alfred Henry Garrod, F.R.S., being desirous of possessing some memorial of him, it has been agreed, after due consideration, that this object will be best effected by the republication in a collected form of all his separate memoirs and papers, both zoological and physiological, prefaced by a biographical notice and portrait of the author. A committee has been formed to carry out this object, consisting of Prof. W. H. Flower, LL.D., F.R.S., P. L. Sclater, Ph.D., F.R.S., Dr. A. Günther, F.R.S., O. Salvin, F.R.S., F. M. Balfour, F.R.S., Prof. E. A. Schäfer, F.R.S., G. E. Dobson, E. R. Alston, Prof. F. Jeffrey Bell, W. A. Forbes, secretary. It is estimated that Prof. Garrod's collected papers will form a volume of about 500 pages, royal octavo, illustrated by twenty-five plates and numerous woodcuts. Each subscriber to the fund will be entitled to receive a copy of the work for every guinea subscribed. Intending subscribers are requested to forward their names, and to state the amount they are willing to subscribe, to the Secretary of the Garrod Memorial Fund, 11, Hanover Square, London, W.

Dr. J. H. Gladstone, F.R.S., has presented 100*l*. to the Research Fund of the Chemical Society.

The French Government has allotted M. Pasteur the sum of 50,000 francs for the purpose of enabling him to carry out his researches on the contagious diseases of animals.

Wishing to devote himself exclusively to scientific pursuits, Admiral Mouchez, director of the Paris Observatory, has asked to be placed on the retirement list, a request which has been granted by the Ministry.

The well-known mathematician, Prof. C. W. Borchardt, died at Rüdersdorf, near Berlin, on June 27. He was formerly Professor of Mathematics in the Military Academy, and of late years Professor in the University of Berlin. Since 1856 he was editor of the *Journal für Pure and Applied Mathematics*, the oldest of the existing mathematical periodicals.

THE death is announced, at the age of fifty-seven years, of Dr. Karl Neumann, professor of history and geography in the University of Breslau; his name is well known to students of historical geography.

AT the *fête* in Paris yesterday the electric light played a prominent part. It was used to illuminate the fountains of the Tuileries Gardens, the upper part of Notre Dame, the Bourse, the dome of the Panthéon, Porte Saint Denis, and several other public places, besides private buildings. One of the most interesting experiments was that of M. Serrin from the top of his house, facing the Place de la République, where the gas companies organised an unrivalled display. M. Serrin has invented an apparatus which has been already tried with great success, and may be moved in any direction with an amazing velocity. His powerful ray of light describes curves in space visible at an immense distance. Some new forms of regulators were exhibited for the first time on this occasion. The *fête*, being national, was celebrated all over France in the 40,000 communes or townships of the Republic, and the electric light was used in the provinces as well as in Paris. The most notable display was probably at Rouen, where a group of sixteen Siemens lights, of a power of about 100,000 candles, was placed on the top of the spire of the Cathedral.

THE several improvements in the National Library of Paris have resulted in a large increase in the number of readers. In 1869, when the new hall was opened, the number of readers was 24,000, who used 71,000 volumes exclusive of the library of reference. In 1879 the number of readers was 63,000, and of volumes used 230,000. It must be added that other libraries are open to the public in Paris and largely frequented, such as the Conservatoire des Arts et Métiers for mechanical science and physics, the Muséum d'Histoire Naturelle for natural history; the Mazarin St. Genevieve, for general purposes; the Sorbonne, École de Droits, École de Médecine, &c., for the general public, as well as for students. Readers are admitted to the National Library reading hall only by tickets; a special room has been opened to the public, and is also largely frequented. The present hall is only provisional, and a new one, on a larger scale will be opened very shortly.

A TRIAL has just been made on the measured mile in Stokes Bay, under the superintendence of the Steam Reserve and in the presence of the Controller of the Navy, of a service steam pinnace propelled by the Mallory screw. This is the first application of the American invention in the English service, and much interest was manifested as to the results of the trial. The propeller, which was fitted to a pinnace constructed specially for the purpose, is capable of being turned to any angle by means of a pinion and gearing, like an ordinary rudder, with which it dispenses. The boiler is stowed away under the forecastle, while the cylinders are placed at the stern and act directly upon the vertical shaft which turns the screw. Six runs were made with the engines going ahead and two with the engines going astern, there being scarcely half a knot's difference in the mean speed realised, 8·828 knots being obtained while going ahead with 339 revolutions, and 8·451 knots going astern with 340 revolutions. The engines were reversed from full speed ahead to full speed astern in ten seconds. But the most remarkable results were obtained in turning, the little craft showing such remarkable handiness that it not only turned in its own length, 42 feet, but was put by Col. Mallory through the movements of a quadrille, chaining, setting to partners, and galloping to places. She made a circle to starboard in thirty-six seconds, and without stopping, made a second circle to port, thus completing the figure 8 in thirty-seven seconds. The trial was deemed satisfactory, but the vibration at the stern was so great that the after part of boats fitted with the Mallory propeller will require to be specially strengthened.

THROUGH the kindness of General Myer we have received some further details concerning the extraordinary memory credited to the man in charge of the hat room at the Fifth Avenue Hotel, New York, referred to in NATURE, vol. xxi. p. 562. He is an Irish-American about thirty years of age, Gilmartin by name, and has occupied his present position about a year. His sole duty consists in looking after hats during meal hours. The fact of his possessing a remarkable memory is indisputable, but still he is not looked upon as a prodigy by the hotel officials. They state that a Tommy Hart, now dead, who figured conspicuously in the "Stokes trial," was for a long time in charge of their hat-room, and was this man's superior as regards memory, and cited other instances of men now employed in different hotels throughout the country whom they consider his equals. It is very evident, however, that he possesses a wonderful talent for selecting the right hats, and mistakes are rare with him.

THE suggestion made by A. Martin with regard to radiometers (*British Journal of Photography*, July 9, p. 312) is a very obvious one, and has been made dozens of times. We believe that soon after Mr. Crookes commenced working with Becquerel's luminous sulphides he tried to get a radiometer to move by means of the light given out by these bodies after insolation. He used them painted on one side of the vanes of a radiometer, and also as luminous screens outside the radiometer to act on the darkened vanes, but it was all to no purpose. The light evolved was too faint to have any effect. It is just possible that if a room were entirely coated internally with Balmain's luminous paint and excited by sunlight or burning magnesium, a radiometer might revolve in it for a short time, but even this is not likely to occur. The most sensitive radiometer will not turn to a candle more than twelve feet off, and the torsion-balance photometer will only just move to a candle thirty feet off; yet the illumination given by a candle at this distance is far greater than any we have seen produced by the luminous sulphides.

FURTHER accounts of the earthquake in Switzerland on Sunday week prove it to have been one of the most severe and widespread which has happened in Switzerland for several years. It was felt in the Central and Pennine Alps, at Berne, Zurich, Payerne, Andermatt, on the Lake of Lucerne, in the Bernese Oberland, in the cantons of Geneva and Vaud, and doubtless in Savoy. The principal seat of disturbance was in the Valais, in the neighbourhood of Visp and Brieg. In both places the shock was preceded and accompanied by aërial noises and underground detonations. The time of its occurrence is variously stated at 9.20 and 9.30 a.m., and the direction of the movement, so far as can be made out, was from south to north. At Leukerbad the shock is said to have been accompanied by subterranean thunder. Further east, in the neighbourhood of Geneva and Lausanne, the oscillation was perceptible only in the upper rooms of houses near the Lake.

AN occurrence, which may be partially or wholly attributable to the rude shakings which Switzerland has recently undergone, is reported by the *Times* Geneva correspondent from Quarten, in the canton of St. Gall. A short time ago the people of the neighbourhood noticed signs of uneasiness about the Schnebelberg. The summit of the mountain appeared to be in a very precarious position, and it was feared that it might slip down and overwhelm the Schnebelwald, an extensive wood in the valley below. In anticipation of a possible catastrophe, great efforts were made to cut down and carry away as many trees as possible, though the men engaged in the work wrought at the peril of their lives. On Sunday fortnight, when fortunately there was nobody in the wood, a deafening report, like the firing of heavy artillery, resounded through the valley, and the mountain was hidden from view by a thick cloud of dust. When it

dispersed, the Schnebelberg was seen to be shorter by a few metres, and the beautiful wood in the Murgthal has disappeared beneath a huge avalanche of stones and earth.

At the annual meeting of the Council of the Royal School of Mines, the prizes and associateships were awarded as follows:—The Edward Forbes medal and prize of books to H. M. Platnauer. The De La Beche medal to John Greene. The Murchison medal and prize of books to H. M. Platnauer. Associates: Mining and Metallurgical Divisions—E. B. Lindon, P. W. Stuart Menteath, Ralph Scott. Mining Division—John Greene, B. Mott, H. E. Tredcroft. Metallurgical Division—R. S. Benson, J. J. Beringer, D. B. Bird, H. S. Cotton, W. Cross, W. L. Grant, G. S. Grundy, C. L. Higgins, B. McNeill, T. H. Reeks, J. Taylor. Geological Division—H. H. Hoffert, H. M. Platnauer.

The Agricultural Society's show at Carlisle, which was opened on Monday, is said to be unusually successful, so far as the exhibits are concerned.

Mr. P. H. Pepys writes:—"It may interest some of your geological readers to know that a branch canal is now in course of being made from the Grand Junction Canal at a point near the West Drayton Station of the Great Western Railway. This cut, which runs parallel with the Great Western Railway to a point not far from the Slough station, passes through beds of river gravel and brick earth, a very interesting section of which has just been opened up by the excavators."

A sad balloon accident has taken place at Le Mans, and may be referred to as illustrating some useful facts relating to aëronautics. A man named Petit had ascended with two balloons connected by a long rope. The smaller, which was placed above, carried his son, almost a boy; Petit being in the larger with his wife. There was not much wind, and this foolish experiment would have ended without accident if Petit had not forgotten to loosen the neck of the balloon, so that no escape was left for the gas which was gradually expanding. When the balloon arrived at an altitude of 400 to 500 metres it burst in the vicinity of the "equator," and descended with great velocity, dragging the smaller balloon. Petit, who was devoid of any scientific knowledge, supposed his son was in danger, and with true heroism he cut the rope connecting the two balloons when at 250 to 300 metres from the ground. He placed his wife on the ring and remained himself in the car. The shock was so terrible that his spinal cord was broken, and he died on the following day. His wife was very badly hurt, and though in danger, is alive. If Petit had not cut the rope by an act of unintelligent devotion he would very likely have escaped, and his son would not even have touched the ground.

We have received the first two parts of Dr. Braithwaite's "British Moss Flora," published by the author at 303, Clapham Road. We hope to notice the work at length on its completion.

From Dr. Schomburgk's Report on the progress and condition of the Botanic Garden and Government Plantations of South Australia during the year 1879, we gather many interesting facts. First, with regard to the climatic changes, temperature, sunshine, &c., and their effects on vegetation in Adelaide. During the Australian autumn, winter, and spring the country was visited with the most favourable and seasonable weather on record, the influence of such a season had, of course, a wonderful effect on the agricultural and pastoral produce of the colony, the wheat crop, for instance, being one of the most abundant on record. We are told that owing to a "part of the spring months—September and October—being cool and cloudy, and showery, the roses flowered in such perfection as was never witnessed in South Australia. Flowers were seen from five to six inches in diameter. On the subject of forage plants, a subject that has occupied a good deal of attention in our colonies of late, *Cyperus esculentus*, known as the chuffa or earth almond, takes a prominent place. This plant it appears is extensively grown in the Southern States of America, where the tubers are used for feeding hogs, sheep, and poultry. These tubers are said to contain a quantity of air and sugar, and are consequently very fattening to animals fed upon them. Dr. Schomburgk also recommends the cultivation of the Nardoo plant (*Marsilea macropus*, Hook.), which, in the interior of South Australia, where the plant is common, forms a valuable nutritious forage plant. Attention is also drawn to the Tagasaste (*Cytisus proliferus*), a shrubby leguminous plant of the Canaries, the leafy branches of which have a reputation as a useful fodder. Dr. Schomburgk announces the probable early completion of the new Museum of Economic Botany in the Botanic Garden, the cases in which are arranged on the plan "adopted in the new Kensington and Kew Museums." The museum collection already numbers 2,000 specimens, and these are being constantly added to, contributions constantly arriving in very large numbers.

The annual meeting of the Royal Society of New South Wales, Sydney, was held May 12; the number of new members elected during the year is fifty-one, making the total number of ordinary members upon the roll to date, 430. During the year the Society has elected the following gentlemen as honorary members, viz.:—Mr. George Bentham, F.R.S., C.M.G., Dr. Charles Darwin, F.R.S., Prof. Huxley, F.R.S., Prof. Owen, C.B., F.R.S., making the total number of honorary members nineteen. Mr. R. Etheridge, jun., F.G.S., has been elected a corresponding member of the Society. Financially the Society's affairs are in a satisfactory condition. At the Council meeting held on April 28 it was unanimously resolved to award the Clarke memorial medal for 1878 to Prof. Owen; for the year 1879 to Mr. G. Bentham; and for 1880 to Prof. Huxley, for their valuable contributions to the knowledge of the palæontology, botany, and natural history respectively of Australia. During the past year the Society has received 664 volumes and pamphlets as donations, against which it has distributed 523 volumes and pamphlets. The honorary secretaries are Prof. Liversidge and Dr. Leibius. At this meeting Sir Joseph Dalton Hooker was elected an honorary member.

METEOROLOGICAL NOTES

Prof. Nipher has sent us the *Missouri Weather Service Report* for April, 1880, and the *Daily Times* of St. Louis of May 4, in both of which publications interesting and valuable details are given of the tornadoes which desolated Marshfield, and were attended with disastrous results at other places in their route through the south-west of the State of Missouri. The details were collected with great labour and care, Professors Nipher and Shepard, Judge Barker, and Messrs. Smith and Kribben having spent four days in the saddle, from the 22nd to the 26th, in collecting the evidence of eye-witnesses and examining the effects produced by the tornado. The Marshfield tornado was one of three whirlwinds which occurred in this part of Missouri, separated only by short intervals of time. The most violent of these began near the south-west corner of the state, and thence swept up the Finley Creek Valley. The width of its path exceeded a mile at points, and over this breadth even oak saplings were torn out by the roots, and either thrown out of its path or laid down in rows in the lee of ridges. The average width of its destructive path for a distance of 100 miles was 3,000 feet, thus covering an area of 60 square miles. The Marshfield tornado originated about half an hour earlier and at a point a little to northward, slightly diverging from the path pursued by the previous tornado. Though less violent, considered as a whole, it proved much more destructive to life, no fewer than sixty persons being killed in the town of Marshfield, that town itself being wholly destroyed. The destructive path of this tornado was about 45 miles in length, and as its average breadth was about 1,500 feet, it covered an area of 13 square miles. This storm

over solid caustic potash, and latterly over sodium. When satisfied that it was free from moisture, oxygen, and sulphur, a tube, $2\frac{3}{4}'' \times 20'' \times \frac{1}{2}''$ bore, was three parts filled, and some charcoal powder added, and the whole welded up solid. I found that the nitrogenous liquid was even worse to work with than the hydrocarbon, as on coming into contact with the hot iron it burnt it away at once, and as the tube was of great diameter it was extremely difficult to keep the lower part cool. For welding it had to be arranged so that it was standing in a tub of ice, and the top projecting through the bottom of the forge, and heated until it was at a welding heat, with as little de'ay as possible. When a tube was obtained welded up solid it was heated to a dull red-heat for 14 hours and allowed to cool; on opening the tube there was a very great out-rush of gas, and the carbon was to a certain extent dissolved, and some minute portions of it very hard. Still, under the microscope it presented little difference in appearance from the wood charcoal employed, some of the features, however, being obliterated, and it had a bright appearance. Another tube of the same dimensions and contents was closed up in the same manner, but after eight hours' heating it burst with a loud explosion. I had noticed that a tube which had been once used and been partially carbonised would not stand a second heating, and for this reason I had no belief in the power of cast-iron or steel to withstand the great pressure at a red heat. Nevertheless, as many of my friends had urged upon me to try these materials, I had a cast-iron tube made, $3\frac{3}{4}'' \times 24'' \times \frac{7}{8}''$ bore, and filled two-thirds of its volume with bone oil distillate and carbon, and then welded up. We succeeded after a little trouble in making a good weld, and the tube was then slowly raised to a dull red-heat in the furnace. It had not been heated for more than an hour when it exploded with a great noise and knocked down the back and one of the ends of the furnace, leaving the whole structure a wreck. The tube had broken into small fragments, and was quite unlike the malleable iron tubes which generally tore up. Thinking that it was perhaps a bad casting, I tried another, but it leaked all over, and emptied itself before the temperature was nearly up. A third tube of the same material burst like the first, but as I had built up the furnace with large blast-furnace blocks, it was not blown down. Cast-iron being inadmissible, experiments were then made with steel. I had several tubes made of this material by the best firms in the kingdom—made by the three methods, Bessemer, Siemens, and the crucible method—but they had the same faults as cast-iron, although to a less degree. The difficulty in making a good weld in cast-iron and steel tubes makes their employment in such experiments as these a matter of inconvenience. Out of five tubes made of steel, some of which were made of the very toughest material manufactured by Messrs. Cammell and Co., only one held in the substance completely. Three burst in the furnace, and one had leaked by its porosity. The top of the furnace, by the continued shocks of explosions, fell in at the bursting of the last of the steel tubes. The continued strain on the nerves, watching the temperature of the furnace, and in a state of tension in case of an explosion, induces a nervous state which is extremely weakening, and when the explosion occurs it sometimes shakes one so severely that sickness supervenes. An account of several experiments follows, none of which were, however, successful.

I thought I should either have to abandon the attempt or begin experiments of a very expensive nature, using large tubes and a large furnace, as 20-inch tubes of a greater diameter than four inches could not be closed when three parts filled—at least by welding. As some of them, however, seemed to stand, I determined to make some further trials with the apparatus I had at my disposal; so another tube, $20'' \times 4'' \times \frac{1}{2}''$ bore was filled, using 4 grms. of lithium and a mixture of bone oil, carefully rectified, 90 per cent., and paraffin spirit 10 per cent., using these proportions because I had never had any results with a high percentage of bone oil, the tubes so filled having burst. The tube was closed with great difficulty, being three-parts full of liquid, and then heated to a visible red heat for fourteen hours, and allowed to cool slowly. On opening the tube a great volume of gas was given off, and only a little liquid remained. In the end of the tube which had been the upper end in the furnace, the tube lying obliquely, there was a hard smooth mass adhering to the sides of the tube, and entirely covering the bottom. As I had never obtained all the solids in one piece before, I wished to examine it, and so had the other end of the tube cut off, exposing the hard mass. It was quite black, and was removed with a chisel, and as it appeared to be composed principally of iron and lithium, it was laid aside for analysis. I was pulverising it in a mortar when I felt that some parts of the material were extremely hard—not resisting a blow, but hard otherwise. On looking closer I saw that these were mostly transparent pieces imbedded in the hard matrix, and on triturating them I obtained some free from the black matter. They turned out to be crystalline carbon, exactly like diamond. I shall describe further on the analyses, &c., but will here go on with the account of my further experiments. Two tubes were filled in the same manner as the last, but one burst on heating, and the other had leaked so that there was no reaction. Two more tubes were prepared, but were spoiled on welding, and on cutting off the carbonised portion the remainder was too short to work. After much trouble three tubes were obtained, well closed, in which the three alkali metals were inclosed with liquid containing 20 per cent. bone oil and 80 per cent. paraffin. All three stood, and, on opening, only the potassium one had leaked to any extent. The results were not good, however, the sodium tube containing only soft scaly carbon, and the other two very little better. The reaction did not seem to have proceeded in the same manner in the lithium tube as before, as the mass was soft and friable. Still, lithium seemed to yield the best results, so it was adhered to in the further experiments. A list of disasters now awaited me. Eight tubes failed through bursting and leaking, and one of the explosions, when two were being heated together, destroyed a part of the furnace and injured one of my workmen. Besides this, two tubes were spoiled in welding. However, I had four experiments after this, all withstanding the pressure, and in one of these, with 10 per cent. bone oil and 90 per cent. paraffin spirit, a small quantity of diamond was found. The contents of this tube were different from the other successful one, being much looser and not in the same hard mass as the first. In another series of six experiments two were at first thought to have been successful, but I afterwards found that one of them was not so, the transparent matter being siliceous, but insoluble in cold hydrofluoric acid, although it dissolved on boiling. The uncertainty and great expense involved in using these forged coils of iron with tubes bored out of the solid induced me to again try steel, and Messrs. Cammell and Co., having prepared some tubes for me, I tried them, but with the same results—they exploded into fragments at a red heat. And herein they are much more dangerous than coiled tubes, because the latter seldom fly into fragments, but just tear open a little. A further unforeseen danger in using steel tubes was discovered. One which had stood the heating very well was being bored, and when the inner skin was cut so that the gas rushed out, the whole exploded, endangering the life of the workman who was boring, but as he was standing at the end of the tube and the pieces flew laterally, he was not hurt. I have performed over eighty experiments, and have only obtained three results of a successful nature. The identification of the crystalline pieces as carbon was easy enough, but I have been anxious to find whether they are pure carbon or a compound with some other element, and to that end the following experiments were conducted.

A portion of the substance from the first successful experiment was weighed out after it had been freed from all foreign matter adhering to it, and placed in a very small platinum boat made of a strip of thin foil, the ends of which were wrapped round two stout platinum wires which were sealed into a wide glass tube. The carbon particles were transferred to this boat after being weighed, and the tube connected by india-rubber stoppers with an oxygen gasometer on the one side and a series of potash bulbs on the other. The oxygen was dried over solid caustic potash before entering the tube, and again after leaving the potash bulbs. The carbon (14 mgrms.) having been weighed out, the potash bulbs were weighed, and a current of oxygen passed through the apparatus, and the platinum wires connected with a battery strong enough to heat the foil to a bright red-heat. After a few minutes the oxygen was stopped and the bulbs weighed, when it was found that they had gained 1 mgrm. On repeating this operation no gain was found, the moisture having been entirely driven off by the first treatment. The carbon was now placed in the boat, and a slow current of oxygen started, then the bulbs connected and the current made to pass through the platinum until all the diamond had been burnt, when the current was stopped and the oxygen allowed to pass for fifteen minutes more, when the bulbs were detached and weighed. They were then reconnected and the gas passed for other ten minutes to find whether all the carbonic acid had been expelled,

and reweighed. They weighed 0·2 mgrm. less than before. The numbers were as follows:—

Potash bulbs before combustion	...	43·8308	
" " after "	...	43·8776	
			·0468
Drying tube before combustion	...	26·4294	
" " after "	...	26·4328	
			·0034
			·0502

This gives a composition of 97·85 per cent. of carbon, which is a pretty fair approximation to pure carbon. However, to determine whether or not this was the case, some further experiments were tried. A small quantity of the carbon was placed on the platinum boat and burnt in oxygen without any of the gas being allowed to pass out of the apparatus, and the mixed gases so obtained transferred to a eudiometer, and the carbonic acid and oxygen absorbed. It was then found that a residue amounting to about 3 per cent. of the carbonic acid was left unabsorbed by alkaline pyrogallate solution. This proved to be nitrogen. A blank experiment was done, but it gave only a minute bubble of nitrogen. Another experiment was performed with the following results:—

Total volume	183·7		
After absorption of CO_2	148·5	CO_2 =	35·2
After " O	1·1	O	147·4
		N	1·1

This plainly shows that nitrogen was present from some cause or another, and as every precaution was taken in transferring the gas from one vessel to another, and as the blank experiment showed nothing, I am inclined to believe that the carbon, or at least some portions of it, contained nitrogen chemically combined. The numbers above given are degrees on the eudiometer tube, and are not more than one-third of a cubic centimetre each. Their exact value was of no consequence in the experiment, and the tube was only calibrated by comparing one part with another, and not with an absolute measure.

From the fact that no diamond was found when nitrogen compounds were absent, and from the fact that the mixed product (for only a portion of the 14 mgrms. was clear diamond) contains nitrogen, I am inclined to believe that it is by the decomposition of a nitrogenous body, and not the hydrocarbon, that the diamond is formed in this reaction. The experiments are, however, too few, and the evidence too vague, to draw any conclusions, as there are even very few negative experiments from which anything can be learned, most of the results being lost by explosion. I intend, when my other work—which I laid aside for the diamond experiments—is finished, to begin a series of experiments on the decompositions of carbon compounds by metals, to find whether a more easily-controlled reaction may not be discovered.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE following circular has been issued by the Science and Art Department:—"It having been represented to the Lords of the Committee of Council on Education that many parts of the kingdom are still in ignorance of the system of aid to the formation of classes for instruction in the principles of agriculture afforded by the Science and Art Department; that the supply of teachers who have obtained the necessary qualification to earn payments on results is very limited; and that a strict adherence to the rules of the Science Directory, which require that, in order to obtain aid, classes must be under the instruction of such teachers, would entail the delay of a year in the commencement of classes in this important subject, my Lords decide that §§ xxxiv. and xxxvi. of the Directory may be relaxed for this year in the following manner:—My Lords will be prepared to consider an application from any committee, formed in accordance with § x. of the Science Directory, to grant a temporary qualification to any person selected by it as fitted to teach the principles of Agriculture, and, if such application be found satisfactory, will permit the teacher to earn payments on the results of the examination in May, 1881; on the condition that this provisional qualification shall then determine, and that the only teachers who can after that date be recognised as qualified to earn payments on the results of their teaching in this subject will be such as have complied with the ordinary rules. In making the application the committee must show that there is no technically qualified teacher in the locality who could be employed to instruct the class, and also state the grounds on which the proposed teacher is considered to be really capable of giving instruction in agriculture, by his knowledge of chemistry and other sciences bearing on the subject."

MR. RICHARD CHARES ROWE, M.A., B.Sc., Fellow of Trinity College, Cambridge, has been appointed Professor of Mathematics in University College, London.

PLANS have been prepared for a new botanical class-room in connection with Edinburgh University, the present room being much too small. The plans have been submitted to Government; if approved there will be a grant for the purpose required. The new class-room proposed will be seated for six hundred students, while the old class-room will be altered so as to be used as a practical and histological class-room.

SOCIETIES AND ACADEMIES

London

Royal Society, May 27.—"A Preliminary Account of the Reduction of Observations on Strained Materials, Leyden Jars, and Voltameters," by John Perry and W. E. Ayrton. Communicated by Prof. G. G. Stokes, Sec. R.S. [Abstract].

In discussing the residual-charge phenomena of condensers, the authors point out that in spite of certain elaborate measurements which have been made on different kinds of glass, nobody has yet discovered a constant such that it expresses the residual charge property of a particular substance. They therefore say that the simple plan of charging a Leyden jar for a long time, short-circuiting for a small definite period, then insulating and giving the residual charge at certain times from insulation (thus getting say three definite numbers for each dielectric experimented upon), is more accurate than, and is just as definite as, any plan hitherto proposed for determining the residual-charge properties of a dielectric. They show that if Prof. Clerk Maxwell is right, the only correct means of studying these properties are given by the constants of Maxwell's differential equation, and they describe experiments on the Leyden jar of a Thomson's electrometer, and reductions of observations to obtain such constants. Thus one such constant is found to satisfy all the observations made from the 500th to the 900th minute of insulation of a jar. The authors draw attention to the analogy which they have pointed out between condensers and voltameters charged by electromotive forces less than one and a half volts, and show that if we assume Maxwell's equation to be true for voltameters, that is, if we assume a voltameter to be a condenser, one constant satisfies observations from the 50th to the 190th minute of charging, and from the 20th to the 80th minute of discharging. They then proceed to develop a theory of the increasing strains in bodies subjected to constant stresses. When a homogeneous substance is suddenly subjected to stress, there is a suddenly produced strain which follows Hooke's law, depending on a constant k, but besides this there is a viscid increase of strain whose rate is proportional to the stress depending on a constant r. In steel the viscous strain is not of much importance, whereas in water strained by bodies moving in it it is very important, as it is also when a beam of sealing wax is loaded. They show that the viscid increase of strain is exactly analogous with the flow of electricity in accordance with Ohm's law, and that the suddenly-produced strain is analogous with induction; and considering a heterogeneous material subjected to shearing stress, they find that the above assumptions lead, for strained materials, to exactly the same equation as Prof. Maxwell found for condensers. They found that the support of this theory is exactly the same as the support which they have given of Maxwell's theory of condensers. Thus one constant of the equation satisfied the recovery from deflection of a glass beam from the 4th to the 240th hour of relief, and satisfied the recovery from twisting of a glass fibre for all but the first few observations. They have also constructed a voltameter such that the platinum electrodes may be maintained at any temperature in an atmosphere of any gas for any length of time, maintaining a vacuum over the liquid or saturating it with any gas, and they give the different values of the residual charge constant, which satisfies all but the first few observations of charge and discharge in different cases. The authors conclude their paper by saying that, regarding a voltameter as a condenser, then as the plates of the charging battery are larger and nearer together, and as the times of charge and discharge of the voltameter are made less and less, the more do the total quantities of the charge and discharge approximate to one another.

Physical Society, June 26.—Prof. W. G. Adams in the chair.—Mr. C. V. Boys read a paper, by Prof. Guthrie and himself, on the measurement of the conductivity of liquids by means of magneto-electric induction. The liquid is suspended in a glass vessel by a fine iron wire in the centre of a cylindrical electro-magnet formed of two semicircular parts. This electro-magnet is rotated at a velocity not exceeding 3,000 turns per minute, and the liquid being drawn round in the direction of rotation, the wire is subjected to torsion, which, under correction for certain errors, is proportional to the resistance of the liquid. The torsion is observed by means of a scale and microscope. The results, plotted in a curve, agree very closely with those of Kohlrausch, obtained by alternate currents, and Dr. Guthrie thinks that they are probably more correct and trustworthy than Kohlrausch's, for the method would seem to be superior and the curve contains fewer excentric points than his.—Dr. Gladstone read a paper on the refraction equivalents of isomeric bodies, in which he described the present state of the subject and his own contributions to it. He showed that the refractive power of bodies over light was of great importance to chemists, since it depended on their essential structure.—Dr. Huggins described his latest results of star spectra, and illustrated his remarks by photographic spectra taken by his improved method. From these it appears certain stars, such as Vega, give a complete spectrum of hydrogen. Others, more yellowish in colour, show a thinning of these lines, such as Sirius, η Ursæ Majoris. Others show the intrusion of more refrangible lines; for example, Arcturus, α Aquila, α Virginius; while Capella gives a complex spectrum like that of the sun. Dr. Huggins also showed a spectrum of the flame of a spirit lamp, which presented a strong group of lines at S, and he considered it to represent the light emitted by the molecules of water. He further observed that the spectrum offered a highly sensitive test of the presence of carbon.—Mr. Liveing exhibited a new fire-damp indicator, capable of detecting ¼ per cent. of marsh gas in air. It is based on the fact that an incandescent body shows more brilliantly in proportion to the amount of marsh gas in the air, and consists of two fine platinum wires kept incandescent by a magneto-electric current sent through them in one circuit. One wire is excluded from the fire-damp, the other is exposed to it, and the relative intensities of the two glowing wires is compared by a photometric screen placed between them and adjustable to a position between them at which the reflections of the wires on the screen are of equal intensity. The position of the screen relatively to the wires is given by a scale, and measures the proportion of fire-damp in the air. This contrivance is more advantageous than the safety-lamp, which only indicates 2 per cent of marsh gas in the air.—Dr. Stone exhibited a vacuum-tube of variable resistance and a large electro-magnet wound with iron wire. The former consists of a barometer-tube thirty-two inches long, terminating above in a short vacuum-chamber arranged transversely, and closed at either end by adjustable india-rubber stoppers, through which platinum terminals are passed. Above this the vertical tube is continued to a glass stopcock, by means of which small quantities of air can be introduced. The foot of the tube is attached to an india-rubber flexible pipe with a cistern like that of Frankland's gas apparatus. The cistern full of mercury is counterbalanced, and can be raised or lowered at will through the whole thirty-two inches. A Torricellian vacuum can thus be made in the upper chamber, or one of more or less perfectness. On passing the induction-spark between the terminals in the former case all the discharge is carried off, none appearing at the discharger. By gradually raising and lowering the cistern, after admitting a little air by the stopcock, the resistance of the partial vacuum thus obtained can be altered within wide limits. A point can also be found where the spark of breaking-contact is shunted through the vacuum-tube, while the weaker discharge of making-contact is stopped. The induction-current is thus obtained in a single direction, a matter of some importance in physiological experiments. The electro-magnet could not be described from pressure of other matter. Its peculiarities consisted in its being wound with best charcoal-annealed wire of about 5 millim. section in four parallel circuits, and in each pole being cast, after winding into a solid block of paraffin. It was expected that the latter device would increase the inductive effect of the spirals; and indeed it appeared that the lifting power was somewhat strengthened. The cores had been originally wound with large copper wire of about the same weight as the iron wire. But the lifting power for batteries of moderate size, five or six Bunsen's cells, for instance, had increased fourfold after the substitution.—A paper by Mr. McFarlane Gray entitled specific heats calculated from entropy. This is a re-affirmation of a paper on the value of v, declined by the committee of the Royal Society in February, 1878. The author read a paper at the last meeting of the Institution of Naval Architects, which we said was a singularly bold and original attempt to account for many of the phenomena of steam and other effects of heat when applied to matter. In the present paper Mr. Gray continues in the same line of startling generalisation. The following is a specimen:—Taking the $p\,v$ of hydrogen at 493°·2 F., as in Rankine's tables, to be 378819 foot pounds, he writes—

$$u = \frac{m p v}{J \theta} = \frac{2 \times 378819}{772 \times 463{\cdot}2} \, 1{\cdot}989856.$$

The letter u in the paper with the value obtained as above is applied in the following remarkable generalisations: m being the molecular weight of the substances, and $p\,v$ and θ being the pressure, volume, and absolute temperature in any standard units.

$$\text{The thermal equivalent of } p\,v = \frac{u}{m}\,\theta.$$

$$\text{Specific heat at constant volume } = 2\tfrac{1}{2}\,\frac{u}{m}\,\theta$$

$$\text{Specific heat at constant pressure } = 3\tfrac{1}{2}\,\frac{u}{m}\,\theta$$

The specific heat in the gaseous state is therefore at constant pressure.

$$\frac{3\tfrac{1}{2} \times 1{\cdot}989856}{17{\cdot}96} = {\cdot}387779$$

for H_2O, water in the gaseous state. By calculating the difference of entropy for water at numerous temperatures for the different states of aggregation, first absolute H_2O without energy volume, secondly, water as we know it with a volume increasing with temperature; thirdly, water split into single molecules, but these yet without motion; fourthly, single molecule H_2O or steam gas; he shows that the difference of entropy between the third and the fourth state is equal to the specific heat at constant pressure, and that the whole energy possessed by the water up to the split and motionless state is a constant quantity at all temperatures for the same substance. He calls this quantity the absolute splitting heat; the splitting heat above any standard state he calls the nominal splitting heat, S a constant quantity for all temperatures. From the entropy calculation for more than twenty temperatures, all calculate to seven places of decimals from Regnault's exact formula (H) for saturated steam, he takes two temperatures indiscriminately, and equates the value of S expressed in entropy quantities with one unknown quantity, the specific heat entropy.

Equating 278° C. with 374° C. gives ...	·387729

or	904·311 F.

This is a remarkable corroboration of the kinetic theory of gases, quite unlooked for in steam experiments, and, as the author of the paper remarked, it shows how reliable are the results of the experimenter Regnault. The author also explained a new diagram, in which the area is energy, the length entropy, and the height temperature. In such a diagram it becomes as simple an idea as temperature. From this it appears that the ratio of the two specific heats is 1·4 for steam.—Mr. Clark communicated a paper on the behaviour of liquids and gases near their critical temperatures.—Mr. Winstanley exhibited two new varieties of air-thermometers and a thermograph actuated by an air-thermometer on the principle of his radiograph exhibited at last meeting. The first thermometer consists of a U tube with terminal bulbs and the left leg of much finer bore than the right. Mercury is in the right leg, sulphuric acid surmounted with air in the left. The apparatus is a barometer to the air inside the left bulb, and a thermometer to that outside. A similar combination of an air-thermometer and an aneroid barometer constitutes the second instrument. The expansion or contraction of the air in the stem by external temperature expands or compresses a small aneroid chamber in the bulb.—Mr. Gee and Mr. Stroud made a communication on a modification of Bunsen's calorimeter, which will be found in the *Proceedings* of the Society.—The meeting then adjourned till the winter session commences.

Geological Society, June 23.—Robert Etheridge, F.R.S., president, in the chair.—Edwin Muir, Benjamin Sykes, and John Thorburn were elected Fellows of the Society. The following communications were read:—On the skull of an *Ichthyosaurus* from the lias of Whitby, apparently indicating a new species (*I. zetlandicus*, Seeley), preserved in the Woodwardian Museum of the University of Cambridge, by Prof. H. G. Seeley, F.R.S.—Note on the cranial characters of a large Teleosaur from the Whitby lias, preserved in the Woodwardian Museum of the University of Cambridge, by Prof. H. G. Seeley, F.R.S.—On the discovery of the place where Palæolithic implements were made at Crayford, by F. C. J. Spurrell, F.G.S.—The geology of Central Wales, by Walter Keeping, F.G.S., with an appendix by C. Lapworth, F.G.S., on a new species of *Cladophora*.—On new Erian (Devonian) plants, by J. W. Dawson, F.R.S. The paper first referred to recent publications bearing on the Erian (Devonian) flora of North-East America, and then proceeded to describe new species from New York and New Brunswick, and to notice others from Queensland, Australia, and Scotland. The first and most interesting is a small tree-fern, *Asteropteris noveboracensis*, characterised by an axial cylinder composed of radiating vertical plates of scalariform tissue imbedded in parenchyma and surrounded by an outer cylinder penetrated with leaf-bundles with dumb bell-shaped vascular centres. The specimen was collected by Mr. B. Wright in the Upper Devonian of New York. Another new fern from New York is a species of *Equisetides* (*E. wrightianum*), showing a hairy or bristly surface, and sheaths of about twelve short acuminate leaves. A new and peculiar form of wood, obtained by Prof. Clarke of Amherst College, Massachusetts, from the Devonian of New York, was described under the name *Celluloxylon primævum*. It presents some analogies with *Prototaxites* and with *Aphyllum paradoxum* of Unger. Several new ferns were described from the well-known Middle Devonian plant-beds of St. John's, New Brunswick; and new facts were mentioned as confirmatory of the age assigned to these beds, as showing the harmony of their flora with that of the Erian of New York, and as illustrating the fact that the flora of the Middle and Upper Devonian was eminently distinguished by the number and variety of its species of ferns, both herbaceous and arborescent. It will probably be found eventually that in ferns, equisetaceous plants, and conifers, the Devonian was relatively richer than the Carboniferous. Reference was also made to a seed of the genus *Aetheotesta* of Charles Brongniart, found by the Rev. T. Broun in the Old Red Sandstone of Perthshire, Scotland, and to a species of the genus *Dicranophyllum* of Grand'-Eury, discovered by Mr. J. L. Jack, F.G.S., in the Devonian of Queensland. In all, this paper added six or seven new types to the flora of the Erian period. Several of them belong to generic forms not previously traced further back than the Carboniferous. The author uses the term "Erian" for that great system of formations intervening in America between the Upper Silurian and the Lower Carboniferous, and which, in the present uncertainty as to formations of this age in Great Britain, should be regarded as the type of the formations of the period. It is the "Erie Division" of the original Survey of New York, and is spread around the shores of Lake Erie, and to a great distance to the southward.—On the terminations of some Ammonites from the inferior oolite of Dorset and Somerset, by James Buckman, F.L.S.—Faröe Islands: Notes upon the coal found at Suderöe, by Arthur H. Stokes, F.G.S.—On some new cretaceous *Comatulæ*, by P. Herbert Carpenter, M.A. Communicated by Prof. P. Martin Duncan, F.R.S.—On the Old Red Sandstone of the north of Ireland, by F. Nolan, M.R.I.A. Communicated by Prof. Hull, F.R.S.—A review of the family Vincularidæ, recent and fossil, for the purpose of classification, by G. R. Vine. Communicated by Prof. P. M. Duncan, F.R.S.—On the zones of marine fossils in the calciferous sandstone series of Fife, by James W. Kirkby. Communicated by Prof. T. Rupert Jones, F.R.S.—The glaciation of the Orkney Islands, by B. N. Peach, F.G.S., and John Horne, F.G.S. In this paper, which forms a sequel to their description of the glaciation of the Shetland Isles, the authors, after sketching the geological structure of Orkney, proceeded to discuss the glacial phenomena. From an examination of the various striated surfaces they inferred that the ice which glaciated Orkney must have crossed the islands in a north-westerly direction from the North Sea to the Atlantic. They showed that the dispersal of the stones in the boulder-clay completely substantiates this conclusion; for in Westray this deposit contains blocks of red sandstone derived from the Island of Eda, while in Shapinsha blocks of slaggy diabase, occurring *in situ* on the south-east

shore, are found in the boulder-clay of the north-west of the island. Again, on the mainland, blocks of the coarse siliceous sandstones which cross the island from Inganess to Orplin are met with in the boulder-clay between Honton Head and the Loch of Slennis. Moreover, they discovered in the boulder-clay the following rocks, which are foreign to the island: chalk, chalk-flints, oolitic limestone, oolitic breccia, dark limestone of Calciferous-sandstone age, quartzites, gneiss, &c., some of which closely resemble the representatives of these formations on the east of Scotland, and have doubtless been derived from thence. From this they infer that, while Shetland was glaciated by the Scandinavian *mer de glace*, Orkney was glaciated by the Scotch ice-sheet, the respective ice-sheets having coalesced on the floor of the North Sea and moved in a north-westerly direction towards the Atlantic. They also found abundant fragments of marine shells in most of the boulder-clay sections, which are smoothed and striated precisely like the stones in that deposit. They conclude that these organisms lived in the North Sea prior to the great extension of the ice, and that their remains were commingled with the *moraine profonde* as the ice-sheet crept over the ocean-bed. From the marked absence of shell-fragments in the Shetland boulder-clay they are inclined to believe that much of the present sea-floor round that group of islands formed dry land during the climax of glacial cold.

Paris

Academy of Sciences, July 5.—M. Edm. Becquerel in the chair.—The death of M. Borchardt (correspondent in Geometry) was announced.—The following papers were read:—Study of the variation of the line of sight, on the great meridian circle of Paris Observatory (constructed by M. Eichens), by means of a new apparatus, by M. Loewy. The essential part is a small glass disk giving simultaneously three images in the eye-piece: (1) that of the cross wires, (2) that of a division drawn on the objective, and (3) that of one of the divisions of a plate inserted in the axis.—On the photography of the chromosphere, by M. Janssen. The exposure is continued till the solar image is positive to the border; the chromosphere then appears as a dark circle 8″ or 10″ in width.—On the integration of linear equations by means of the sines of superior orders, by M. Villarceau.—On the consequences of the experiment of MM. Lontin and de Fonvielle, by M. Jamin. He indicates experiments which should test his explanation.—On the vision of colours, by M. Chevreul.—On some general relations between the chemical mass of elements and the heat of formation of their combinations (continued), by M. Berthelot. The influence of mass of the elements in diminishing the stability, and therefore the heat liberated, may be conceived simply by supposing that the system formed by two molecules will be more exposed to destruction by movements of the whole system (rotations, vibrations, &c.,) the heavier the molecules. On the other hand, the reserve of energy (which is gradually expended in combination), should, *ceteris paribus*, be greater in light elements than in heavy ones.—Epochs of vegetation for the same tree in 1879 and in 1880, by M. Duchartre. Though the temperature was much more severe in December and January last than the previous year, the renewal of vegetation in six chestnuts was earlier. The mild time between the cold of December, 1879, and January, 1880, does not account for this, for a longer and milder time intervened in 1878–79. Nor does the method of sums of heat explain it. But the trees received more heat this year from the beginning of vegetation to complete expansion of their leaves.—On a meteorite which fell on November 16, 1874 at Kerilis (Côtes du Nord), by M. Daubrée. This belonged to the sub-group Oligosideres in the Sporadosideres.—On a meteorite which fell on September 6, 1841, in the vineyards of Saint Christophe-la-Chartreuse (Vendée), by M. Daubrée.—Inquiry into the situation of agriculture in France in 1879, by M. Chevreul.—On the utility of quarantines, by M. de Lesseps. He gives examples of their inadequacy.—Nature of the immunity of Algerian sheep against spleen-disease; is it an aptitude of race? by M. Chauveau. The property is congenital and natural. It may be communicated by crossing to European sheep. French sheep bred in Algeria do not acquire it, and it is not proved that Algerian sheep bred in France may not lose it.—Determination of the difference of longitude between Paris and Bonn, by MM. Le Clerc and De Bernardières. The figures obtained are 19m. 2·269s., probable error ± 0·009s. German astronomers found for the same arc, 19m. 2·231s.—Some remarks on the equation of Lamé, by M. Escary.—Integration of any number of simultaneous equations between a given number of functions of two independent variables and their partial derivatives of the first order, by M. Turquan.—On the bright spectral lines of scandium, by M. Thalén.—Improvements in Siemens' bobbins, by M. Trouvé. He suppresses the two periods of indifference, making the polar faces of snail form, so that the surfaces approach those of the magnet gradually, till the moment that the posterior edge escapes from the pole, when repulsion commences. The work is thus economised.—On the sensibility of the eye to differences of light, by M. Charpentier. A given light, strong or weak, must (in his case) be increased or diminished about eight hundredths to give a distinct new sensation; and it seems to be the same in indirect vision as in direct, and with coloured as with white light.—Thermic study of polysulphides of ammonium and persulphide of hydrogen, by M. Sabatier.—On the density of iodine vapour, by M. Troost. He finds it to diminish both at a low and at a high temperature, so that dissociation or isomeric change seems hardly admissible.—On the atomic weight and on some characteristic salts of ytterbium, by M. Nilson.—On the dissolution of platinum in sulphuric acid, by M. Scheurer-Kestner. The attack of platinum is always due to presence of nitrogenised compounds in the sulphuric acid.—Remarks on etherification of hydracids, by M. Villiers.—Atmospheric bacteria, by M. Miquel. The number, very small in winter, increases in spring, and is high in summer and autumn; but while spores of mould are abundant in wet, and rare in dry, periods, it is the opposite with aërial bacteria. At Montsouris, in summer and autumn, 1,000 germs of bacteria are sometimes found in 1 cubic metre; in winter the number may go down to 4 or 5, and on some days 200 litres of air are insufficient to infect the most alterable liquors. In ordinary houses air proves fertilising (to neutral bouillon) in a volume of 30 to 50 litres. M. Miquel notes an increase of deaths from contagious and epidemic diseases in Paris, about eight days after a recrudescence of aërial bacteria. Water vapour from the ground, rivers, or putrefying masses is always micrographically pure.—On a digestive ferment contained in the sap of the fig, by M. Bouchut.—A work by M. de Koninck, on the fauna of the carboniferous formation of Belgium, was presented.

Vienna

Imperial Academy of Sciences, May 7.—B. Bolzano's significance in the history of infinitesimal calculation, by Prof. Stolz.—Investigation of the roast products of coffee, by Herr Bernheimer.—On direct introduction of carbonyl groups into phenols and aromatic acids (third part); behaviour of pyrogallic and gallic acids with carbonate of ammonia, by Prof. Senhofer and Dr. Brunner.—On Guthrie's cryohydrates, by Herr Offen.—On the relation of the coefficients of diffusion of gases to the temperature, by Herr von Obermayer.—On the coincidence of disorders of the skin and of the grey axis of the spinal cord, by Dr. Jarisch.

VICTORIA UNIVERSITY

IT was only the singular moderation and good sense with which the promoters of the New Manchester University movement conducted their case that could have secured that no Parliamentary opposition should be made to the late Government taking a step so momentous, and affecting so many rival interests, as the foundation of a new English university. They were compelled, indeed, like many other strategists, to change front once or twice, and to accept a charter different in two vital respects from that which they had asked. They wanted a university in England on the model of the Scotch and German universities—a university of a single college in a great centre of population. They were compelled, however, to make provision for affiliating Leeds and other colleges, when they become adequately equipped, with full faculties of arts and science, and when it is completed the new University will have to carry out an experiment completely novel. It will occupy a midway place between the Scotch single-college universities, the English universities with their families of colleges bound together by their common locality, and the Central Examining Board for all qualified applicants, which is known as the University of London. The separate colleges will in fact be Universities of the Scotch type, complete in themselves before they are affiliated in respect of two important faculties. They will differ vitally from the single colleges of Oxford and Cambridge, each with three or four tutors of its own, but each requiring to lean on the private tutors and the resident university professors and lecturers for the necessary supplement of their teaching. It will be most interesting to see how the University authorities will conciliate the independence and originality of the teaching of the individual colleges with the examination system which must govern and regulate them all. The new University will more nearly resemble the late Queen's University in Ireland than anything else of which we have had experience. It will differ from the Queen's University only in the greater importance of the separate colleges. Meanwhile all these arrangements are *in posse*. The University will be started on the familiar lines of the Scotch and German universities, with a single college, with which for the time being it is practically identified, and whose teaching it will be its sole business to influence.

The other important modification is in the temporary absence of the medical faculty. An important medical school is attached to Owens College. The last Government were occupied with a Medical Bill, the main object of which was to diminish the number of licence-granting medical centres, and to substitute a single authority for the nineteen medical bodies which confer the right to practise on the bodies of Her Majesty's subjects. It was strongly represented to them that it would be an anomaly that they should add a twentieth licensing body to the nineteen at the very moment when they were attempting to fuse the nineteen into one. The charter they have issued to the Victoria University grants it the right to confer all degrees and titles of honour that it is competent to other universities in the United Kingdom to grant, except in the single faculty of medicine. Although the medical professors of Owens College become professors in the University, they will remain in an exceptional position, at all events until the new Government have made up their minds what course to adopt with the Medical Bill. Should the agitation for a medical uniformity die out, and the Government resolve upon no disturbance of the existing arrangements, it will be impossible for them not to complete the charter of the new University by conferring on it the right to grant medical degrees. Should they revive the proposals of their predecessors and succeed in passing them into law, the new University will stand in the same position as that which the older universities will then be reduced to occupy.

The public will be most interested to see on what lines the Victoria University will be developed. Will it strike out a new line for itself? Every university in this country aims at being a *studium generale*, but every university has in practice shown a tendency to the exceptional development of special studies. Oxford is in the main a great classical, and Cambridge a great mathematical, school, and London has been exceptionally distinguished for the high attainments and reputation of its medical graduates. In the Victoria University, so far as it is possible to forecast its future, a similar position seems likely to be asserted by the scientific faculty. It is in that respect that Owens College has been specially strong. In all the older universities the scientific faculties have had to assert for themselves a higher position than they originally occupied, and they have generally done so during the last century of their history. They will start in the Victoria University from a position at least equal to that occupied by the elder "Arts" studies. It would be a mistake if they were to attempt to claim an exclusive predominance, and the first step which the University has taken indicates that there is no such danger. They have appointed as their Chairman of the Board of Studies their Professor of History and English Literature. Every one who has followed the movement in which the University originated knows how deeply it has been indebted, from its commencement to its close, to Prof. Ward, and it is safe to say that no sounder appointment could have been made, and none more likely to secure the impartial appreciation of all the competing claims of the old and the new learning. The authorities of the Victoria University will begin their new career on the broad and satisfactory lines indicated by the words of their founder. Mr. Owens' will pointed to the creation in Manchester of a seat of learning in which the subjects taught in the English universities should be taught in the best way, and the promoters of the movement have never advocated any scheme for making themselves a scientific college, or what is called a technical university. But it will be as difficult as it would be imprudent to ignore the fact that Manchester has special opportunities for becoming a great scientific school, and the eminent teachers who represent its scientific faculty may be confidently trusted to maintain the position which they have secured for their subjects. We may reasonably hope to see the new University set itself to the task of proving that science is as educationally effective an instrument as literature and philosophy. Literature,

history, and language will hold their own adequate place in its scheme of instruction, but the newer sciences of animate and inanimate nature will certainly start from a fairer platform than usual, in the North of England. The Victoria University will not be hampered, like its elder sisters, by the traditions of the past. There is a great career before it, and the people of England will watch its development with the deepest interest. They may be reasonably confident of one thing, that the new educational "brand," to adopt Prof. Huxley's felicitous expression, will be of as select a character as any of the "brands" with which they are familiar.

ON THE RELATION BETWEEN THE MOLECULAR WEIGHTS OF SUBSTANCES AND THEIR SPECIFIC GRAVITIES WHEN IN THE LIQUID STATE

UNDER this title I have communicated to the Chemical Society the results of a prolonged investigation on the connection existing between the weights of unit volumes of liquid substances and their relative molecular weights (see *Journal* of the Chemical Society for March, April, May, and June, 1880), and in obedience to a request from the Editor of NATURE I will briefly indicate the scope of the inquiry, and point out the main conclusions to which I have been led. The inquiry, I may say in the outset, has resolved itself into a critical and experimental examination of what are known as Kopp's laws of specific volume. That some definite connection between molecular weight and specific gravity would be traced had been surmised more than forty years since, but all our exact knowledge on the subject is contained in the series of classical memoirs which we owe to Hermann Kopp. Kopp first clearly recognised the necessity of comparing the liquids when under strictly analogous conditions. By dividing the specific gravity of a liquid taken at the temperature at which its vapour-tension is equal to the standard atmospheric pressure—that is, at its ordinary boiling-point—into its molecular weight, we obtain its specific volume. If the specific gravity be referred to the point of maximum density of water, this value represents the number of cubic centimetres occupied by the relative molecular weight of the liquid expressed in grams at its boiling-point under the standard pressure. The numbers thus obtained were first shown by Kopp to exhibit certain definite relations which may be briefly stated as follows :—

I. *In many instances differences in specific volume are proportional to differences in corresponding chemical formulæ.*—Thus a difference of CH_2 in a homologous series corresponds to a difference of about 22 in the specific volume, or $(CH_2)x = 22x$. On comparing the specific volumes of similarly constituted haloïd compounds, it is seen that the substitution of n atoms of bromine for an equal number of chlorine atoms increases the specific volume by $5n$.

II. *Isomeric and metameric liquids have, as a rule, the same specific volume.*—Exceptions are exhibited by certain oxygen and sulphur compounds.

III. *The substitution of an atom of carbon for two of hydrogen makes no alteration in the specific volume of certain groups of organic liquids.*

On the basis of these conclusions Kopp was able to calculate certain numerical values for the specific volumes of the elements in combination. These values are as a rule constant for the particular element: thus, according to Kopp, carbon has invariably the value of 11, hydrogen that of 5·5. Exceptions are observed in the case of the chemical analogues oxygen and sulphur. Each of these bodies has two values depending, it would seem, on its mode of combination, or on its relation to the remaining atoms in the molecule. For example, acetone and allyl alcohol have each the empirical formula C_3H_6O, but the specific volume of acetone is 78·2, whilst that of allyl alcohol is 73·8. In the case of acetone the combining power of the oxygen atom is wholly satisfied by carbon; that is, we have reason to know that the oxygen atom is more intimately associated with one of the carbon atoms than it is with any one of those of the other elements; whereas in allyl alcohol a moiety of the combining value would seem to be satisfied by carbon and the remainder by hydrogen. It appears, then, that when oxygen is united to an element by both its affinities its specific volume is 12·2; when it is attached by only one combining unit its specific volume is 7·8. The corresponding values for sulphur are 28·6 and 22·6.

I have already pointed out that these differences in the values for the specific volumes of oxygen and sulphur may be employed to throw light upon the constitution of such bodies as the phosphoryl and thiophosphoryl compounds, and that we may in this way obtain evidence as to the particular affinity-value that an element such as phosphorus, which is variously regarded as a triad and a pentad, exerts, and in the present paper I give additional instances to show that a knowledge of the specific volume of a body is often calculated to furnish valuable information concerning its constitution.

The most accurate method of ascertaining the specific volume of a liquid is (1) to determine its specific gravity at some convenient temperature; (2) to ascertain its boiling-point with the utmost exactitude; and (3) to determine with great care its rate of expansion, say between 0° and this boiling-point.

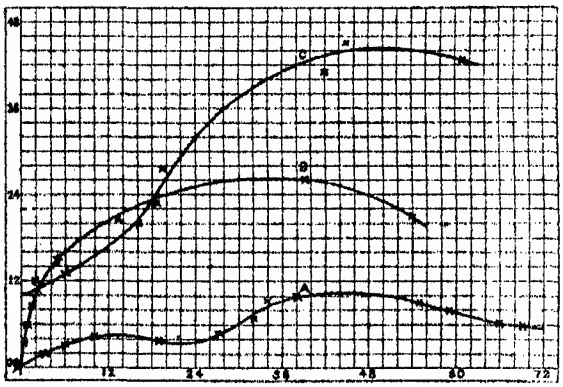
The space at my disposal forbids me attempting to show how these various physical data were determined for the purpose of the present inquiry. Full details of the methods employed are given in the original paper, and the errors incidental to the various processes are fully discussed. The observations necessitated among other things the frequent determination of the fixed points of the thermometers employed, and the accompanying figure shows how these were found to rise during the progress of the investigation. The abscissæ represent the times in months at which the several observations were taken, and the ordinates the extent of displacement in hundredths of a degree. A represents a thermometer ranging from − 10° to 50° C., B from 50° to 105° C., and C from 98° to 144° C. It will be seen that the extent of the displacement is evidently dependent on, or at any rate is greatly influenced by, the amount of molecular disturbance to which the glass envelope is subjected.

The accuracy of the results is of course in great measure dependent upon the purity of the liquids employed, and this fact to some extent limited the number of compounds which could be investigated. Whenever the mode of

preparation was not a sufficient guarantee of the purity it was established either by analysis or by the determination of its vapour density—a most rigid test, provided that this could be ascertained with sufficient accuracy. I have ventured to modify the original form of the Gay-Lussac-Hofmann apparatus, and I think I may claim that this modification admits of all the precision which the process is capable of yielding. It obviates some of the disadvantages of the original method, such as the liability to crack the tube, and the use of a large quantity of mercury and of liquid to vaporise the body under investigation, and it also permits of a more certain application of the necessary corrections.

Among the many problems suggested by a review of our present knowledge of the subject, the following seemed to me to be specially worthy of solution.

I. Is it definitely established that an element in combination has as a rule an invariable specific volume? May not the volume be modified by the number of the atoms of that particular element in the molecule? Is it



Curves showing rise of fixed points in thermometers.

altogether independent of the general complexity of the molecule, or may not the specific volume of the molecule be a function of its weight?

II. Do the various members of a family of elements possess identical specific volumes, or may not the volume be a function of the atomic weight?

III. Would a re-examination of the cases of so-called variable atomic value serve to show that the specific volume of an element is a function of that value, as Buff supposes?

IV. The hypotheses of Mendelejeff and Meyer indicate the need of additional and more exact determinations of the values for the specific volumes of the elementary bodies?

This scheme of work required the determination of the specific gravities, boiling-points, and thermal expansions of about fifty liquids, and the results of the observations afford material for the calculation of the specific volumes of seventeen elementary bodies. The rates of expansion are represented by formulæ of the form—

$$V = A + Bt + Ct^2 + Dt^3.$$

The labour of reducing the observations, and more especially of calculating the empirical formulæ for so large a number of substances, has been materially lightened by the use of the arithmometer of Thomas (de Colmar). The investigation has therefore incidentally added very considerably to the data upon which the determination of the general laws affecting the thermal expansion of liquid bodies must depend.

After a discussion of the errors of the observations and a comparison of my results with those obtained by previous observers, whenever these were applicable, I have summarised the main conclusions to which I have been led as follows:—

1. It seems certain that many isomeric liquids, even of the same chemical type (using that phrase in the sense in which it is employed by Kopp) have not identical specific gravities at their respective boiling-points, and hence have not identical specific volumes. Such exceptions are more commonly met with in compounds containing carbon and hydrogen; this fact appears to indicate that the specific volume of one or both of these elements is not absolutely invariable. Benzene derivatives especially show a greater departure from the general law than can be fairly attributed to experimental error. Their variations are of the same order as has been shown to occur in the refraction values for these compounds.

2. We must also suppose that of the additional elements, oxygen, sulphur, and nitrogen have likewise variable specific volumes in conformity with Kopp's conclusions.

3. There is at present no experimental evidence for assuming that any other element has a variable specific volume.

4. Hence in the case of these elements the volume is not modified by the number of the atoms of the particular element in the molecule, and it is therefore altogether independent of the general complexity of the molecule.

5. The different members of a family of elements do not possess identical specific volumes; the volumes of the elements are periodic functions of their atomic weights.

6. The inquiry affords no evidence in support of the hypothesis that the specific volume of an element in combination is modified by any possible variation in the affinity value which it may possess. T. E. THORPE

GORDON'S "ELECTRICITY AND MAGNETISM"

A Physical Treatise on Electricity and Magnetism. By J. E. H. Gordon. (London: Sampson Low and Co., 1880.)

THE author, in the first paragraph of his preface, draws a distinction between the physical and mathematical points of view in treating the Science of Electricity. Unfortunately, the distinction is at present a real one. Many mathematicians, fascinated by the beauty of the instruments they handle, are disposed to treat physical problems as though the principal function of the universe were to suggest problems to the pure mathematician, instead of the principal function of the pure mathematician being to provide suitable tools for solving physical problems. On the other hand, there are skilful experimentalists who fail to appreciate those powerful methods of deductive quantitative reasoning which they are themselves unable to handle. Mr. Gordon does not profess to be a mathematician, and adopts the experimental point of view.

The book makes no claim to be a complete treatise, but rather to deal with those branches of the science with which the author is best acquainted, one might almost say, those parts at which he has himself worked, either originally or by way of verifying the work of others. As might be expected from such a scheme, the descriptions of apparatus and phenomena are admirable, but, unfortunately, the theoretical explanations, intended to give the book more or less the character of a systematic treatise, are neither clear nor accurate. So early as page 2 we read: "It is found that if equal quantities of the electricity of glass and the electricity of sealing-wax be added together they neutralise each other." But this is not preceded by any explanation of what is meant by equal quantities of the electricities of glass and sealing-wax. If the sentence had been cast as a definition, it would have been comprehensible. On page 20 there is an extraordinary illustration of the medium supposed to transmit electrostatic forces:—

"The transmission of strain may be very beautifully seen at any railway-station when shunting is going on, if a train of carriages is being pushed by an engine which happens, instead of giving a steady pressure, to strike a slight blow on the carriage nearest to it. The furthest carriage does not move at once, but the buffer springs are compressed—that is, the first carriage is for an instant strained by having its total length shortened by some inches. It instantly recovers from this strain by the expansion of the springs; but as it cannot expand towards the engine, it expands away from it, and transmits the strain to the next carriage by compressing its buffer-springs, and the process is repeated all the way from the engine to the carriage furthest from it."

This buffer experiment is an illustration of wave-motion, an idea we do not need in any theory of electrostatics. On page 23 there is a popular explanation from the pen of Prof. Ayrton of the easy discharge of electricity from points; this remarkable explanation does not in any way depend on the greater electric surface density at and near a point, and it suggests that the force near a conductor is *not* normal to its surface. It is unnecessary to pursue this criticism further; we have said enough to show that Mr. Gordon's strength does not lie in the systematic exposition of electrical theory.

The book is divided into four parts—Electrostatics, Magnetism, Electrokinetics, and Electro-optics. In the third part is included all the phenomena of current electricity. This is an unsatisfactory classification. Electrokinetics should be confined to those phenomena of current electricity which involve the kinetic energy of current, such as electromagnetism and electromagnetic induction. The author would have been wiser to have followed the arrangement of Maxwell, and have classed the steady flow of electricity in conductors at rest rather with electrostatics than electrokinetics. Adams's experiments on equipotential lines and surfaces in conductors are interpolated between diamagnetism and the induction coil; they are, of course, naturally a part of the theory of electrical resistance, and have no near connection with the chapter preceding or following.

Great care has been bestowed on the illustration of the work. We know of no book on electricity so beautifully illustrated. Nor are the pictures merely pictures. They show well the details of apparatus; often, too, some leading dimensions are given when perspective does not admit of a scale. We would recommend this practice to all writers on science. It is a great help to the imagination to know how large a thing is, and better that this information should be upon the picture than in the text only.

In the construction of this book the freest use has been made of the scissors, whole pages being quotations. This is both wise and modest, for when the original works of the man who discovered and stated a fact are suitable for a treatise, there can be no use in paraphrasing them. Some of the chapters are excellent analyses of the several investigations which have been made into the subjects of which they treat. This is notably the case with the chapter on "Specific Inductive Capacity." When Mr. Gordon has occasion to prepare a new edition he will do well to expand where he is strongest, to omit as far as possible systematic exposition, but to make each chapter a history to which the reader may refer with confidence that he will there find a clear account of every original experiment, English or foreign, that has been tried in that department. The value of such a work would be inestimable.

STRATIGRAPHICAL GEOLOGY

Lethæa geognostica, oder Beschreibung und Abbilding der für die Gebirgs-Formationen bezeichnendsten Versteinerungen. Herausgegeben von einer Vereinigung von Paläontologen. I. Theil: *Lethæa palæozoica*, von Ferd. Roemer. Textband: Erste Lieferung. Pp. 324. (Stuttgart, 1880.)

THE study of fossils may be approached from two distinct points of view: we may regard them as furnishing us with additional illustrations of the diversities of form and structure in the animal and vegetable kingdoms, or we may study them as making their appearance in a certain definite order, and thus as characterising particular geological formations. The former is the point of view of the biologist, the latter that of the stratigraphical geologist. Palæontology, or the study of fossil forms, must necessarily be pursued as a branch of biology, for only by the study of their nearest recent analogues can we hope to interpret the fragmentary and often obscure relics of former inhabitants of the globe; but, on the other hand, the progress of systematic geology has been bound up with the study of fossils ever since it has been clearly recognised that strata can be identified by the organic remains which they contain.

German scientific literature is now being enriched by the publication of two very valuable works in which fossils are treated of, in the one case from the stand-point of the biologist, in the other from that of the stratigraphical geologist. The admirable treatise on palæontology by Zittel and Schimper gives an excellent account of the chief types of fossil plants in their relations to living forms, and the work of which we have placed the title at the head of the present article, promises to supply an equally important contribution to stratigraphical geology.

The title of "Lethæa Geognostica" was first employed by Bronn, who between the years 1835 and 1837 published a work under this name, in which he described all the

fossil genera then known in the several geological formations. This book, which was accompanied by an excellent atlas of plates, passed through three editions during the author's life-time, but in the preparation of the last of these he was aided by Dr. Ferdinand Roemer.

The number of fossil forms now known to geologists is so vast that it would be impossible to find any palæontologist competent to deal equally well with the faunas and floras of all the geological periods; and hence it has been decided to commit the palæozoic, the mesozoic, and the tertiary divisions of the work to different hands. Dr. Ferd. Roemer has been selected to describe the life-forms of the palæozoic rocks, and in the work before us we have the first instalment of the result of his labours.

The work commences with a sketch of the succession and correlation of the palæozoic strata in all the different areas in which they have been studied. The author divides these rocks into the four groups of Silurian, Devonian, Carboniferous, and Permian, using the term Silurian, after the manner of Murchison, to embrace all the lower palæozoic strata. This plan is, of course, open to the objection that his first division is at least equal in value to the other three put together. The account of the palæozoic strata as developed in different areas, which extends to ninety-two pages, is generally very carefully drawn up. We notice on pages 11 and 29 an unfortunate error in the grouping together of the Lower Llandeilo and the Tremadoc slates, while in his account of the succession of strata in Sweden the author has failed to avail himself of the most recently-published results arrived at by the palæontologists of that country.

The next twenty pages of the work are devoted to the palæontological literature of the palæozoic rocks, 146 pages to the palæozoic plants, and seventy-seven pages to the Protozoa. The author describes each genus, and gives also an account of some of the more important species. In noticing the earliest palæozoic plants, Roemer follows Schimper in regarding the puzzling forms from Bray Head, called *Oldhamia* by Edward Forbes, as belonging to the Algæ. With regard to the so-called *Eozoon canadense* of Dawson, Dr. Ferd. Roemer accepts the verdict of Möbius against its organic origin, and rejects it from the list of palæozoic fossils.

The atlas of the "Lethæa Palæozoica" was published four years ago, the plates, sixty-two in number, being well executed and of the same size as the text, thus getting rid of the inconvenient arrangement in the former work, where the text was in 8vo, and the plates in folio. It would almost appear as if the atlas were drawn up previous to, and quite independently of, the present work, so that the connection between the illustrations and the text is not so close as might be wished. We cannot help remarking, too, that unless much greater expedition is used in publishing the remainder of the work, the earlier portions will become obsolete before the later portions make their appearance.

Although the atlas appeared in 1876, the text has now only just reached the commencement of the Cœlenterata. Possibly some unavoidable cause of delay has arisen, which, we may hope, is now removed. We look forward with interest to the completion of this most valuable work.

OUR BOOK SHELF

A Treatise on Elementary Dynamics, for the Use of Colleges and Schools. By William Garnett, M.A. Second Edition. (Cambridge: Deighton and Co., 1879.)
